

The structural phase transition and loss of magnetic moments in NpO_2 : *ab initio* approach to the crystal and mean field

A.V. Nikolaev* and K.H. Michel

Department of Physics, University of Antwerp, UIA, 2610, Antwerpen, Belgium

(Dated: February 1, 2008)

We discuss the triple- $\bar{q}^x$ structures for the ordered cubic phase of NpO_2 , which are $Pn\bar{3}m$ and $Pa\bar{3}$. A special care should be taken to discriminate between these two cases. We analyze the relevant structure-factor amplitudes and the effect of domains on resonant X-ray scattering experiments. We formulate the technique of multipole expansion of the Coulomb interaction and use it to study the crystal electric field and mean field for a number of neptunium many electron configurations ($5f^3$, $7s5f^3$, $7p5f^3$ and $6d5f^3$) on *ab initio* level. We have found that the crystal field is rather small (50-150 K). The direct quadrupole-quadrupole interaction between neighboring neptunium sites is weak and can not drive the structural phase transition at 25 K. We have introduced an effective (enhanced) quadrupole interaction and considered the interplay between it and the crystal electric field. The influence of both interactions on the transition temperature has been investigated in detail for the $5f^3$ configuration. We discuss the importance of the intrasite multipole interaction between three localized electrons ($5f^3$) and a valence electron on a neptunium site. We show that this interaction combined with the symmetry lowering at 25 K may be responsible for the loss of the magnetic moments in the ordered phase of NpO_2 .

I. INTRODUCTION

Since the discovery of the low temperature phase transition in NpO_2 at $T_c = 25.5$ K almost fifty years ago,¹ the magnetic properties of this compound represent a challenge for theoretical interpretation.^{2,3} NpO_2 and its neighbor in the actinide series, UO_2 ,^{4,5} are both crystalized in the cubic fluorite (CaF_2) structure in the high temperature phase. The temperature dependence of the magnetic susceptibilities of these compounds is suggestive for a Néel transition to an antiferromagnetic state.^{4,6} However, while it was found that UO_2 orders antiferromagnetically ($T_N = 30.8$ K) with $1.74\mu_B/\text{U atom}$,⁴ no magnetic ordering⁷ was confirmed for NpO_2 (see for a review Ref. 3). As follows from Mössbauer experiments⁸ the upper limit on the magnetic moments of Np in the ordered phase is only $0.01\mu_B/\text{Np}$. This implies almost a complete quenching of the $3.0\mu_B$ magnetic moment of Np, which it exhibits in the paramagnetic high temperature phase. The demagnetization of Np magnetic moments seems to be incompatible with the widely accepted viewpoint that the Np cations are in the tetravalent valence state, Np^{4+} , with three localized $5f$ electrons left at each neptunium site. With the $5f^3$ configuration, Np becomes a Kramers ion having a magnetic doublet (Γ_6 , Γ_7) or quadruplet (Γ_8) ground state. Because of this, a divergent susceptibility at $T \rightarrow 0$ will be present in any model of the phase transition.^{3,9}

To describe the disappearance of magnetic moments of Np at $T < T_c$ Santini and Amoretti put forward an idea of a magnetic octupole order parameter,⁹ which on one hand, is not invariant under time reversal symmetry and, on the other hand, is different from the magnetic dipolar order parameter which brings about the ordinary magnetic ordering. The idea of breaking down of Kramers'

degeneracy by the magnetic octupole seems to be the only solution in the framework of the $5f^3$ model.^{3,9}

An alternative explanation was offered by Friedt *et al.*⁸ They suggested that the magnetic anomaly in NpO_2 could be explained by a splitting of the ground state Γ_8 quadruplet of cubic symmetry into two doublets in the crystal field of lower symmetry of the ordered phase. The splitting was ascribed to an internal distortion of the oxygen sublattice at T_c . This viewpoint was inspired by the experimental observation that the phase transition in UO_2 is accompanied by an internal distortion of the oxygen cube that surrounds the U cation,¹⁰ while the external cubic structure of uranium dioxides survives the transition. However, the mechanism mainly weakens the magnetic response from the Np sites at 20 K, while the $T \rightarrow 0$ divergence of magnetic susceptibility still persists in the model in contradistinction with experiment.^{6,7} On the other hand, no evidence for an internal or external crystallographic distortion in NpO_2 has been found by synchrotron experiments.¹¹ Thus, the phase transition in NpO_2 appears to be isostructural like the $\gamma - \alpha$ phase transition in elemental cerium^{12,13} ($T_c \sim 100$ K) or the isostructural expansion in YbInCu_4 at $T = 42$ K.¹⁴ It is worth mentioning that *in all these compounds the phase transition is accompanied by a loss of magnetic moments in the ordered phase.*

However, very recent resonant X-ray scattering (RXS) experiments at the Np M_{IV} and M_V edges in NpO_2 indicated an unexpected result: the phase transition is not isostructural.¹⁵ In the low temperature phase a long range order of Np electric quadrupoles was revealed by the growth of superlattice Bragg peaks.^{11,15} The space symmetry of the ordered phase was identified as $Pn\bar{3}m$.¹⁵ The symmetry lowering is a special one. The centers of mass positions of neptunium and oxygen remain in the

cubic CaF_2 structure as in the high temperature phase. However, electronic quadrupoles of the Np sites have four different orientations, which allows us to distinguish four different sublattices of Np cations.¹⁵

This experimental finding gives rise to a question of correlations between structural and magnetic properties in solids, which we have investigated theoretically in our model of the $\gamma - \alpha$ phase transition in Ce.^{16,17,18} Unlike NpO_2 , pristine cerium is a metal and the phase transition there at normal pressure is accompanied by a huge volume change.^{12,13} The volume anomaly in NpO_2 (contraction) is only 0.018%.¹¹ However, the disappearance of the magnetic moments and the “isostructural” character of the phase transition makes them similar. In this respect it is interesting to notice that in our model for Ce we have predicted the $Pa\bar{3}$ space symmetry for the ordered α phase¹⁶ which is very close to the $Pn\bar{3}m$ structure reported for NpO_2 in Ref. 15. The active irreducible representation also belongs to the X point of the Brillouin zone (BZ). While the existence of superstructure reflections for α -Ce remains an open question which has to be investigated experimentally,^{16,17,18} here we want to apply our theoretical concepts for the study of the crystal- and mean-field in neptunium dioxide.

We will use the technique of multipole expansion of the Coulomb interaction.^{16,17,18,19} The multipole expansion represents a unified description of the crystal field effects and atomic term splitting. The intrasite Coulomb repulsion which is responsible for Hund’s rules, the spin-orbit coupling and the crystal field effects are included on equal footing. (For a single site the technique is equivalent to the classical description of atomic terms.²⁰) In order to calculate the corresponding electronic spectra we use many Slater determinants, which indicates that our scheme is a genuine many electron approach^{18,19} corresponding to the configuration interaction (CI). (Notice that ordinarily used single-determinant Hartree-Fock approach is not sufficient for these purposes).

The paper is organized as follows. In Sec. II we discuss the triple- $\vec{q}^X$ structures ($Pn\bar{3}m$ or $Pa\bar{3}$) of the ordered phases and derive the selection rules for resonant X-ray scattering (RXS) experiments. In Sec. III we describe our method for treating local electron configurations at neptunium sites. Next (Sec. IV) we examine thoroughly the case of three localized $5f$ electrons. In Sec. V we generalize the $5f^3$ model by including the multipole interactions with a valence electron which is present instantaneously on a Np site. We show that in the framework of this extended model the disappearance of the magnetic moments can be understood and ascribed to the trigonal symmetry lowering at 25 K. Our conclusions are summarized in Sec. VI.

II. STRUCTURAL PHASE TRANSITIONS AND RXS EXPERIMENTS

In this section we discuss the allowed space groups of the low temperature phase of NpO_2 . Our considerations here are based on a general group theoretical approach which is independent of the model assumptions.

In the disordered phase ($T > 25$ K) the crystal structure is cubic ($Fm\bar{3}m$) and the site group is O_h . The electron density of neptunium is given by the spherically symmetric component (Y_0^0) and the cubic harmonics $K_l(\Omega)$ with $l = 4, 6$. There is no contribution to the density from the quadrupole functions $Y_{l=2}^\tau$, where $\tau = 0, (m, c)$ or (m, s) , $m = 1, 2$. (Here and below we work with the real spherical harmonics with the phase definition of Ref. 21.) At $T_c = 25$ K the transition to a new phase sets in. The new phase was characterized as a triple- $\vec{q}$ antiferro- quadrupolar ordering of T_{2g} (Γ_{5g}) electric quadrupoles at the Np sites.¹⁵

In real space the ordering is characterized by four different sublattices of the simple cubic structure. We label these sublattices which contain the sites $(0,0,0)$, $(a/2)(0,1,1)$, $(a/2)(1,0,1)$ and $(a/2)(1,1,0)$ by $\{\vec{n}_p\}$, $p = 1 - 4$, respectively. The most significant feature of the ordered phase is the existence of only one three-fold axis of symmetry C_3 at each Np site which is also a cube diagonal. The only quadrupole function compatible with the symmetry lowering is $Y_2^0(\Omega')$ in the coordinate system where the z' -axis coincides with one of the three-fold axes (cube diagonals): $[111]$, $[-1, -1, 1]$, $[1, -1, -1]$, and $[-1, 1, -1]$. Consequently, there are four such functions which are given by

$$\mathcal{S}_a(\Omega) = \frac{1}{\sqrt{3}}(Y_2^{1s}(\Omega) + Y_2^{1c}(\Omega) + Y_2^{2s}(\Omega)), \quad (2.1a)$$

$$\mathcal{S}_b(\Omega) = \frac{1}{\sqrt{3}}(-Y_2^{1s}(\Omega) - Y_2^{1c}(\Omega) + Y_2^{2s}(\Omega)), \quad (2.1b)$$

$$\mathcal{S}_c(\Omega) = \frac{1}{\sqrt{3}}(Y_2^{1s}(\Omega) - Y_2^{1c}(\Omega) - Y_2^{2s}(\Omega)), \quad (2.1c)$$

$$\mathcal{S}_d(\Omega) = \frac{1}{\sqrt{3}}(-Y_2^{1s}(\Omega) + Y_2^{1c}(\Omega) - Y_2^{2s}(\Omega)). \quad (2.1d)$$

The spherical harmonics Y_2^{1s} , Y_2^{1c} , Y_2^{2s} belong to a three-dimensional irreducible representation T_{2g} of O_h . They are proportional to the Cartesian components yz , zx , and xy .

In Ref. 15 the space group of the ordered phase was identified as $Pn\bar{3}m$ (No. 224, Ref. 22). The corresponding ordering of $\mathcal{S}_a - \mathcal{S}_d$ functions is shown in Fig. 1, left panel. However, a close examination reveals that there is another possibility which was not considered by the authors of Ref. 15. This is the $Pa\bar{3}$ structure (No. 205 of Ref. 22) depicted in the right panel of Fig. 1. The $Pa\bar{3}$ structure also realizes a triple- $\vec{q}$ quadrupolar order, the site symmetry of the Np sites is $S_6 = C_3 \times i$.

The problem of finding the appropriate space group can be simplified to the task of distributing four orientational functions $\mathcal{S}_a - \mathcal{S}_d$ among four distinct sublattices.

FIG. 1: $Pn\bar{3}m$ and $Pa\bar{3}$ structures for quadrupoles of NpO_2 . Both structures have the common S_6 (or $\bar{3}$) local site symmetry. They differ in the way the threefold axes and quadrupoles are distributed over 4 sublattices $\{n_p\}$, $p = 1 - 4$, (see text for details). The $Pn\bar{3}m$ structure possesses three mirror planes one of which (m) is shown explicitly.

tices $\{\vec{n}_p\}$, $p = 1 - 4$. Keeping the three-fold rotation symmetry about the $[111]$ axis and S_a for the first sublattice, we distinguish only three different choices here. The first is when (i) S_b corresponds to $\{\vec{n}_4\}$, $S_c - \{\vec{n}_2\}$, and $S_d - \{\vec{n}_3\}$. This gives the $Pn\bar{3}m$ structure, Fig. 1, left panel. Another assignment is (ii) $S_b - \{\vec{n}_2\}$, $S_c - \{\vec{n}_3\}$, and $S_d - \{\vec{n}_4\}$. This scheme corresponds to the $Pa\bar{3}$ structure as shown in Fig. 1, right panel. The third choice is (iii) $S_b - \{\vec{n}_3\}$, $S_c - \{\vec{n}_4\}$, and $S_d - \{\vec{n}_2\}$. This is simply another variant (or domain) of the $Pa\bar{3}$ structure.

From the mathematical point of view we are analyzing the symmetry lowering and the condensation schemes at the X point of the BZ of the fcc lattice, which involves the density components of the T_{2g} symmetry. In both cases ($Pn\bar{3}m$ and $Pa\bar{3}$) the triple- $\vec{q}$ mode which drives the structural phase transition belongs to the X point of BZ $^*\vec{q}^X$, and involves the three arms of the latter, $\vec{q}_x^X = (2\pi/a)(1, 0, 0)$, $\vec{q}_y^X = (2\pi/a)(0, 1, 0)$, and $\vec{q}_z^X = (2\pi/a)(0, 0, 1)$. To describe the three quadrupolar components $S_1 = Y_2^{1s}$, $S_2 = Y_2^{1c}$, $S_3 = Y_2^{2s}$ at site $\vec{n}$ we introduce the functions $S_i(\vec{n})$ ($i = 1 - 3$) and consider their Fourier transforms,

$$S_i(\vec{q}) = \frac{1}{\sqrt{N}} \sum_{\vec{n}} e^{i\vec{q} \cdot \vec{X}(\vec{n})} S_i(\vec{n}), \quad (2.2)$$

where the position vector $\vec{X}$ runs over N sites of the face centered cubic (fcc) neptunium lattice. The little group of $^*\vec{q}^X$ is D_{4h} ($4/mmm$). At $\vec{q}_x^X$ the functions S_2 and S_3 belong to the E_g small representation, while the function S_1 belong to the B_{2g} small representation. Consequently, we distinguish two different irreducible representations of the space group $Fm\bar{3}m$. The first one, X_5^+ in notations of Stokes and Hatch,²³ comprises six orientational functions, with two functions from every arm of $^*\vec{q}^X$. The functions are $S_2(\vec{q}_x^X)$, $S_3(\vec{q}_x^X)$; $S_1(\vec{q}_y^X)$, $S_3(\vec{q}_y^X)$; $S_1(\vec{q}_z^X)$, and $S_2(\vec{q}_z^X)$. The second irreducible representation, X_4^+ ,

has only three components, with one function from each arm of $^*\vec{q}^X$, namely $S_1(\vec{q}_x^X)$, $S_2(\vec{q}_y^X)$ and $S_3(\vec{q}_z^X)$. For the symmetry lowering to the $Pn\bar{3}m$ structure we obtain the following condensation scheme:

$$\begin{aligned} Fm\bar{3}m : X_4^+ \\ (\langle S_1(\vec{q}_x^X) \rangle = \langle S_2(\vec{q}_y^X) \rangle = \langle S_3(\vec{q}_z^X) \rangle = \rho_1 \sqrt{N} \neq 0) \\ \rightarrow Pn\bar{3}m \quad (Z = 4). \end{aligned} \quad (2.3)$$

Here $\langle \dots \rangle$ stand for a quantum and thermal average and ρ_1 is the order parameter amplitude. The X_4^+ active representation corresponds to the irreducible star $\{\vec{k}_{10}\}$ and the loaded one-dimensional representation $\hat{\tau}^7$ in Kovalev's notation.²⁴ There are four domains for the $Pn\bar{3}m$ structure.

The condensation scheme for the $Pa\bar{3}$ structure is given by

$$\begin{aligned} Fm\bar{3}m : X_5^+ \\ (\langle S_3(\vec{q}_x^X) \rangle = \langle S_1(\vec{q}_y^X) \rangle = \langle S_2(\vec{q}_z^X) \rangle = \rho_2 \sqrt{N} \neq 0, \\ \langle S_2(\vec{q}_x^X) \rangle = \langle S_3(\vec{q}_y^X) \rangle = \langle S_1(\vec{q}_z^X) \rangle = 0) \\ \rightarrow Pa\bar{3} \quad (Z = 4) \quad \text{domain I.} \end{aligned} \quad (2.4)$$

Here again ρ_2 is the order parameter amplitude. This condensation scheme corresponds to a domain shown in Fig. 1, and there are eight possible domains of $Pa\bar{3}$. In particular, there is a domain (iii) which we have already considered before ($S_a - \{\vec{n}_1\}$, $S_b - \{\vec{n}_3\}$, $S_c - \{\vec{n}_4\}$, and $S_d - \{\vec{n}_2\}$) when we analyzed the variants of distribution of $S_a - S_d$ over four sublattices. This domain is obtained as a result of the following symmetry breaking

$$\begin{aligned} Fm\bar{3}m : X_5^+ \\ (\langle S_3(\vec{q}_x^X) \rangle = \langle S_1(\vec{q}_y^X) \rangle = \langle S_2(\vec{q}_z^X) \rangle = 0, \\ \langle S_2(\vec{q}_x^X) \rangle = \langle S_3(\vec{q}_y^X) \rangle = \langle S_1(\vec{q}_z^X) \rangle = \rho_2 \sqrt{N} \neq 0) \\ \rightarrow Pa\bar{3} \quad (Z = 4) \quad \text{domain II.} \end{aligned} \quad (2.5)$$

Previously the symmetry change $Fm\bar{3}m \rightarrow Pa\bar{3}$ has been considered in a number of publications, Refs. 16,17,25, 26. The X_5^+ active representation is defined by the star $\{\vec{k}_{10}\}$ and the loaded two-dimensional representation $\hat{\tau}^9$ in Kovalev's notation.²⁴

Although the two structures look similar there is one very important difference between them. The $Pa\bar{3}$ ordering corresponds to an effective attraction of the quadrupoles, while the $Pn\bar{3}m$ ordering results in a repulsive interaction between them, see Appendix A for details. This is the main reason why the $Pa\bar{3}$ structure (but not $Pn\bar{3}m$) is found in many molecular solids such as H_2 , N_2 ,²⁷ NaO_2 ,²⁵ and C_{60} .^{26,28,29,30,31} Here we speak about the direct bilinear electronic quadrupole-quadrupole interaction. However, in case of NpO_2 there are indirect (superexchange³²) interactions via oxygen which may lead to an effective attraction and therefore, the $Pn\bar{3}m$ structure can not be ruled out. Nevertheless, the $Pa\bar{3}$ space group is a good candidate for the symmetry of the

ordered phase of NpO_2 . Provided that the superexchange interaction remains the same for two structures, the $Pa\bar{3}$ symmetry becomes preferable. It is interesting to notice that at first the symmetry of the ordered phase of the pristine C_{60} molecular crystal was identified as $Pn\bar{3}$.³¹ Only later it was corrected and proved to be $Pa\bar{3}$.^{28,29,30}

Now we will study how the $Pn\bar{3}m$ and $Pa\bar{3}$ structures manifest themselves in resonant X-ray scattering experiments.^{15,33} The tensor of scattering on the quadrupolar density of a neptunium atom in a cubic lattice is given by^{34,35,36}

$$\hat{f}_n = \tilde{f} \begin{pmatrix} 0 & \rho_1 & \rho_2 \\ \rho_1 & 0 & \rho_3 \\ \rho_2 & \rho_3 & 0 \end{pmatrix}, \quad (2.6)$$

where $\rho_i = \pm 1$. We have the following correspondence^{35,36} between the functions $\mathcal{S}_n$, Eq. (2.1a-d), and the scattering tensors: the function $\mathcal{S}_a$ corresponds to $\hat{f}_a$, where $\rho_1 = \rho_2 = \rho_3 = 1$, the function $\mathcal{S}_b$ to $\hat{f}_b$ with $\rho_1 = 1, \rho_2 = \rho_3 = -1$; the function $\mathcal{S}_c$ to $\hat{f}_c$ with $\rho_1 = \rho_2 = -1, \rho_3 = 1$; and $\mathcal{S}_d$ to $\hat{f}_d$ with $\rho_1 = \rho_3 = -1, \rho_2 = 1$. The scattering tensor structure amplitude is found as

$$\mathcal{F}(h, k, l) = \sum_{n=1}^N \hat{f}_n e^{i\vec{K} \cdot \vec{X}(n)}, \quad (2.7)$$

where $\vec{K} = (2\pi/a)(h, k, l)$ stands for the vectors of the reciprocal lattice and a is the cubic lattice constant. In performing the summation in (2.7) we distinguish four contributions from four sublattices $\{n_p\}$, $p = 1 - 4$. We are mainly interested in superstructure Bragg reflections. We obtain then that in general

$$\mathcal{F}(h, k, l) = \tilde{F} \mathcal{M}, \quad (2.8)$$

where $\tilde{F} = \tilde{f}N$ and the matrix $\mathcal{M}$ is either A, B , or C :

$$A = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}, \quad C = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}. \quad (2.9)$$

In Table I we quote which of the matrices (A, B, C) occurs for every particular case of (h, k, l) for the $Pn\bar{3}m$ and $Pa\bar{3}$ structures. We recall that the conditions²² for the isotropic scattering on the fcc lattice of Np (from the spherically symmetric densities) are $h + k, k + l = 2n$, that corresponds to two first lines of Table I.

Finally, we consider the polarization dependencies for resonant X-ray scattering experiments. We assume that a crystal has a flat (001) surface and the azimuthal angle ψ is counted from the x -axis defined by $\vec{e}_x = (1, 0, 0)$.¹⁵ The incident beam direction is given by $(-\cos \Theta \cos \psi, -\cos \Theta \sin \psi, -\sin \Theta)$, the scattered beam direction by $(-\cos \Theta \cos \psi, -\cos \Theta \sin \psi, \sin \Theta)$. We introduce the

TABLE I: Tensor $\mathcal{F}(h, k, l) = \tilde{F} \mathcal{M}$ for the superstructure Bragg reflections on quadrupolar densities of Np. $\mathcal{M} = A, B$ or C , Eq. (2.9), I (ii) and II (iii) refer to two domains of the $Pa\bar{3}$ structure described in the text, 0 is the zero matrix.

Bragg reflection	$Pn\bar{3}m$	$Pa\bar{3}$	
h, k, l :	(i)	I (ii)	II (iii)
$h, k, l = 2n$	0	0	0
$h, k, l = 2n + 1$	0	0	0
$h = 2n + 1, k, l = 2n$	A	C	B
$k = 2n + 1, h, l = 2n$	B	A	C
$l = 2n + 1, h, k = 2n$	C	B	A
$h, k = 2n + 1, l = 2n$	C	B	A
$h, l = 2n + 1, k = 2n$	B	A	C
$k, l = 2n + 1, h = 2n$	A	C	B

TABLE II: The structure factor amplitudes $F_{p \rightarrow p'}(h, k, l)/\tilde{F}$ for four polarization channels of RXS and the matrices A, B and C .

$p \rightarrow p'$	A	B	C
$\sigma \rightarrow \sigma$	0	0	$-\sin(2\psi)$
$\sigma \rightarrow \pi_f$	$\cos \Theta \cos \psi$	$-\cos \Theta \sin \psi$	$\cos(2\psi) \sin \Theta$
$\pi_i \rightarrow \sigma$	$\cos \Theta \cos \psi$	$-\cos \Theta \sin \psi$	$-\cos(2\psi) \sin \Theta$
$\pi_i \rightarrow \pi_f$	0	0	$\sin(2\psi) \sin^2 \Theta$

standard polarization vectors $\vec{e}_i$ ($i = 1 - 3$) parallel ($\vec{\pi}_i$, $\vec{\pi}_f$) or perpendicular ($\vec{\sigma}$) to the scattered plane,

$$\vec{\sigma} = (-\sin \psi, \cos \psi, 0), \quad (2.10a)$$

$$\vec{\pi}_i = (-\sin \Theta \cos \psi, -\sin \Theta \sin \psi, \cos \Theta), \quad (2.10b)$$

$$\vec{\pi}_f = (\sin \Theta \cos \psi, \sin \Theta \sin \psi, \cos \Theta). \quad (2.10c)$$

A structure factor amplitude $F(h, k, l)$ is found as^{34,35,36}

$$F_{p \rightarrow p'}(h, k, l) = \tilde{F} \vec{e}_{p'}^T \mathcal{M} \vec{e}_p, \quad (2.11)$$

where T stands for transpose and $p \rightarrow p'$ denotes one of the four polarization channels, $\sigma \rightarrow \sigma$, $\sigma \rightarrow \pi_f$, $\pi_i \rightarrow \sigma$, and $\pi_i \rightarrow \pi_f$. The structure factor amplitudes for the three cases ($\mathcal{M} = A, B, C$) are quoted in Table II. The corresponding intensities of the superstructure Bragg reflections are found as $I_{p \rightarrow p'}(h, k, l) = |F_{p \rightarrow p'}(h, k, l)|^2$.

From Tables I and II one can easily obtain all necessary dependencies for intensities of different polarizations. For example, the intensity of the (003) reflection of $Pn\bar{3}m$ is exactly the same as the intensity of the same polarization of the (300) reflection of domain I (ii) of $Pa\bar{3}$, and the intensity of the (030) reflection of domain II (iii) of $Pa\bar{3}$. Furthermore, the (013) reflection of domain I (ii), and the (103) reflection of domain II (iii) of $Pa\bar{3}$ also have the same intensity, and so on. Since both symmetries are very similar, we believe that special care should be taken to discriminate between the $Pn\bar{3}m$ and $Pa\bar{3}$ structures.

Tables I and II are also useful in considering the contributions from the domains of the same group. We start with the $Pn\bar{3}m$ structure. The four domains differ by the orientation of the $Y_2^0(\Omega')$ quadrupolar function at

$\vec{n} = 0$. This function may be chosen to align along four main cube diagonals, which are connected with each other through rotations by $\pi/2$ about the z -axis. Hence, all four domains are obtained from the first, (i), by applying three consecutive rotations by $\pi/2$ about the z -axis. The effect of the domains in RXS experiments is equivalent to a superposition of four structure amplitudes, Table II, with angles ψ , $\psi + \pi/2$, $\psi + \pi$, and $\psi + 3\pi/2$. (Here we suggest that the domains produce the coherent scattering.) We label these domains by indices $d1 - d4$, and introduce their populations, $P_{d1} - P_{d4}$. The population of a domain d is defined as $P_d = N_d/N$, where N_d is the total number of neptunium atoms in the domain. Then we obtain from Eq. (2.11) that the structure amplitude for the $\sigma \rightarrow \sigma$ and $\sigma \rightarrow \pi_f$ channels of the (003) reflection is given by

$$F_{\sigma \rightarrow \sigma}(003) = -\tilde{F} \tilde{P} \sin(2\psi), \quad (2.12a)$$

$$F_{\sigma \rightarrow \pi_f}(003) = \tilde{F} \tilde{P} \cos(2\psi) \sin \Theta, \quad (2.12b)$$

where

$$\tilde{P} = (P_{d1} - P_{d2} + P_{d3} - P_{d4}). \quad (2.12c)$$

If $P_{d1} + P_{d3} = P_{d2} + P_{d4}$, $\tilde{P} = 0$ and the (003) Bragg reflection is suppressed. Otherwise, the ψ - and Θ -dependencies in (2.12a,b) are exactly the same as for a single domain, Tables I, II. For the (300) reflection of $Pn\bar{3}m$ one obtains that

$$F_{\sigma \rightarrow \pi_f}(300) = \tilde{F} P' \cos \Theta \cos(\psi + \psi_0), \quad (2.13a)$$

where

$$\psi_0 = \arccos([P_{d1} - P_{d3}]/P'), \quad (2.13b)$$

$$P' = \sqrt{[P_{d1} - P_{d3}]^2 + [P_{d2} - P_{d4}]^2}. \quad (2.13c)$$

Comparing this result with the expression for a single domain, we observe that the main effect is the phase shift ψ_0 given by Eq. (2.13b). The condition for suppression of the reflection is $P_{d1} = P_{d3}$ and $P_{d2} = P_{d4}$. The polarization dependencies of the other reflections of $Pn\bar{3}m$ can be figured out analogously.

There are eight domains of $Pa\bar{3}$ structure. Earlier we have already considered the two basic variants of $Pa\bar{3}$: I (ii), and II (iii). The others are obtained by rotating these two variants by the angles $\pi/2$, π , and $3\pi/2$ about the z -axis. Applying the rotations to I and II, we arrive at two series. We label the population of the series of domains by the indices $P_{d1}^I - P_{d4}^I$, and $P_{d1}^{II} - P_{d4}^{II}$, respectively. The two series result in two distinct scattering matrices, for example, for (003) they are B and A , for (300) C and B , etc, see Table I. The domain pattern produces a superposition of 8 terms (amplitudes). Each term corresponds to one of the two matrices and to one of the four azimuthal angles: ψ , $\psi + \pi/2$, $\psi + \pi$, and $\psi + 3\pi/2$. The relevant expressions are obtained in the same way which we have used to derive Eqs. (2.12a-c)

and (2.13a-c). For example,

$$F_{\sigma \rightarrow \pi_f}(003) = 0, \quad (2.14a)$$

$$F_{\sigma \rightarrow \pi_f}(003) = \tilde{F} \cos \Theta (-P'^I \sin(\psi + \psi_0^I) + P'^{II} \cos(\psi + \psi_0^{II})), \quad (2.14b)$$

The latter expression can be transformed to a shifted $\sin$ - or $\cos$ - like functions, i.e. $F_{\sigma \rightarrow \pi_f}(003) \sim \cos \Theta \sin(\psi + \psi_0')$, where ψ_0' is a phase shift depending on the domain pattern of $Pa\bar{3}$. P'^I , P'^{II} , and ψ_0^I , ψ_0^{II} are given by Eq. (2.13c) and (2.13b), where P_{di} ($i = 1 - 4$) are replaced by P_{di}^I or P_{di}^{II} . For the (300) reflection of $Pa\bar{3}$ we find

$$F_{\sigma \rightarrow \sigma}(300) = -\tilde{F} \tilde{P}^I \sin(2\psi), \quad (2.15a)$$

$$F_{\sigma \rightarrow \pi_f}(300) = \tilde{F} \tilde{P}^I \cos(2\psi) \sin \Theta - \tilde{F} P'^{II} \sin(\psi + \psi_0^{II}) \cos \Theta. \quad (2.15b)$$

Here again $\tilde{P}^I$ is given by (2.12c) for P_{di}^I , $i = 1 - 4$. As before, the superstructure Bragg reflections are suppressed in the case of equal population of 8 domains in the crystal.

III. CONFIGURATION INTERACTION CALCULATION

In this section we describe in detail how we construct the basis consisting of many determinantal wave functions for a many electron system and how we calculate the relevant matrix elements. First, we perform a band structure calculation in order to determine the conduction electron charge distribution in the muffin-tin (MT) sphere around Np. Subsequently, we apply the configuration interaction method to treat the many electron system consisting of the localized $5f^3$ electrons and the conduction electron in the MT sphere.

A. Electron band structure calculation

We have started by performing an electron band structure calculation of NpO_2 using our linear augmented plane wave (LAPW) code.³⁷ The calculation has been done assuming the muffin-tin (MT) shape of the one-electron potential and the Barth-Hedin expression for exchange,³⁸ which is a variant of the local density approximation (LDA). The equal MT radii $R_{MT}^{Np} = 2.2206$ and $R_{MT}^O = 2.2206$ in atomic units (a.u.) were chosen for Np and O, with the cubic lattice constant $a = 10.2567$ a.u. (or 5.4276 Å).¹¹ The MT potential and density of Np and O have been obtained self-consistently using a LAPW basis of ~ 300 functions on a 20-point mesh of the irreducible part of the Brillouin zone. The three $5f$ electrons of Np were treated as core states, which adjust self-consistently to the conduction electron density.

As a result of the calculation we obtained that NpO_2 is an insulator, with the energy gap $\Delta E = 0.789$ eV.

TABLE III: Angular-momentum-decomposed (partial) electronic charges Q_i^A and total charges Q^A inside neptunium and oxygen MT spheres and in the interstitial region (LAPW calculations, see Ref. 39 for details and definitions); $Q^{Np} = -(2Q^O + Q^i)$.

A	Np	O	interstices/per unit
Q_s^A	0.041e	0.027e	—
Q_p^A	0.401e	4.313e	—
Q_d^A	0.261e	0.046e	—
Q_f^A	2.185e	0.011e	—
Q^A	+4.108 e	-0.284 e	-3.540 e

The width of the occupied electron band below the Fermi level is $E_T - E_B = 5.953$ eV. The spin-orbit splitting between $5f_{7/2}$ and $5f_{5/2}$ one-electron states is $\Delta_f = 0.983$ eV. The main goal of the calculation however was the electron charge density distribution inside the neptunium MT-sphere. The calculated partial charges of different angular symmetry ($l = 0 - 3$) are quoted in Table III. An important result is that on average there is approximately one conduction electron present inside the Np MT-sphere. Therefore, the localized $5f^3$ configuration of Np can not be considered separately from this valence electron, which can be of $7s$, $7p$ or $6d$ type. The instantaneous configuration at the neptunium site becomes $7s5f^3$, $7p5f^3$ or $6d5f^3$.

In all cases this additional electron experiences a strong Coulomb repulsion with the three localized partners. This interaction is not fully accounted for by the band structure calculations because it requires a multideterminant treatment or configuration interaction (CI).¹⁸ Therefore, we have to follow a different route and below we study the electron spectrum using the multipole expansion of electronic densities.

B. Many electron basis states

Our method of multipole expansion of the Coulomb interaction has been used before.^{16,17,18,19} Here we formulate it in detail for the sf^3 configuration following Refs. 18,19. In Sec. IV we deal with the $5f^3$ configuration which is easily obtained from sf^3 by omitting one s electron. In Sec. V we consider $7s5f^3$, $7p5f^3$ and $6d5f^3$ configurations. For the latter two cases we will describe the important differences with sf^3 .

We start by considering a face centered cubic (fcc) crystal of N Np atoms. Each atomic site possesses one $7s$ and three $5f$ electrons. The position vector of an electron near a crystal lattice site $\vec{n}$ is given by

$$\vec{R}(\vec{n}) = \vec{X}(\vec{n}) + \vec{r}(\vec{n}). \quad (3.1)$$

Here $\vec{X}(\vec{n})$ is the lattice vector which specifies the centers of the atoms (Np-nuclei) on a rigid fcc lattice. The radius vector $\vec{r}(\vec{n})$ is given in polar coordinates by $(r(\vec{n}), \Omega(\vec{n}))$,

where r is the length and $\Omega = (\Theta, \phi)$ stands for the polar angles. We label the basis ket-vectors at the lattice site $\vec{n}$ by a single index I or, alternatively, by four one electron indices $(i_1^f, i_2^f, i_3^f, i^s)$:

$$|I\rangle_{\vec{n}} = |i_1^f, i_2^f, i_3^f, i^s\rangle_{\vec{n}}. \quad (3.2)$$

The index $i^f = (m^f, s_z^f)$ stands for the orbital ($m^f = 1 - 7$) and spin projection ($s_z = \pm 1/2$) quantum numbers of one f electron. Therefore, there are 14 states which we label by $i^f = 1 - 14$. Two states of the s electron are labeled by $i^s = 1, 2$. The many electron basis wave functions are

$$\langle \vec{r}_1, \vec{r}_2, \vec{r}_3, \vec{r}_4 | I \rangle_{\vec{n}} = \frac{1}{\sqrt{N_a}} \sum_a (-1)^{P(a)} \times \prod_{t=1}^3 \langle \vec{r}_t | i_t^f \rangle_{\vec{n}} \cdot \langle \vec{r}_4 | i^s \rangle_{\vec{n}}, \quad (3.3)$$

where a stands for a permutation of four electrons, the factor $(-1)^P$ takes into account the parity of the permutation, N_a is the number of the permutations, and

$$\langle \vec{r} | i^f \rangle_{\vec{n}} = \mathcal{R}_f(r(\vec{n})) \langle \hat{n} | i^f \rangle, \quad (3.4a)$$

$$\langle \vec{r}' | i^s \rangle_{\vec{n}} = \mathcal{R}_s(r'(\vec{n})) \langle \hat{n}' | i^s \rangle. \quad (3.4b)$$

Here $\mathcal{R}_f$ and $\mathcal{R}_s$ are the radial components of the $5f$ and $7s$ electrons, respectively; $\hat{n}$ stands for $\Omega(\vec{n})$. The $5f$ spin-orbitals can be written as

$$\langle \hat{n} | i^f \rangle = \langle \hat{n} | m_f \rangle u_s(s_z(f)), \quad (3.5)$$

Here u_s is the spin function ($s = \pm$). The f -orbital parts, $\langle \hat{n} | m_f \rangle$, are expressed in terms of spherical harmonics $Y_l^m(\Omega) = \langle \hat{n} | l, m \rangle$. We find it convenient to work with real spherical harmonics²¹ Y_l^τ , where $\tau = 0, (m, c)$ or (m, s) .

The order of indices in (3.2) is important. For example, as follows from the dynamical equivalence of the electrons the state $|i_1^f, i_2^f, i^s, i_3^f\rangle$ can be reduced to $|i_1^f, i_2^f, i_3^f, i^s\rangle$ by permuting the third and the fourth electrons, i.e.

$$|i_1^f, i_2^f, i^s, i_3^f\rangle = -|i_1^f, i_2^f, i_3^f, i^s\rangle, \quad (3.6)$$

and so on. To describe the same quantum state we will use the basis vectors (3.2) and apply the permutation law (3.6) when needed. Alternatively, one can use the corresponding Slater determinants for the four electron wave functions, Eq. (3.3). However, the permutation relations of the type of Eq. (3.6) are more efficient for our purposes. Excluding equivalent states, we find only $(14 \cdot 13 \cdot 12/3!) \times 2 = 728$ independent functions, or determinants, for $7s5f^3$. (These are 364, 2184 and 3640 for $5f^3$, $7p5f^3$, $6d5f^3$, respectively.) Notice, that every basis wave function is in fact a Slater determinant, Eq. (3.3).

C. Multipole repulsion between electrons

Now we take into account the Coulomb intrasite and intersite repulsion by expanding the interaction in multi-

pole series. As was discussed in Ref. 18, these interactions are treated exactly in the chosen quantum space ($7s5f^3$).

The Coulomb interaction between two electrons at sites $\vec{n}$ and $\vec{n}'$ is given by

$$V(\vec{R}(\vec{n}), \vec{R}'(\vec{n}')) = \frac{1}{|\vec{R}(\vec{n}) - \vec{R}'(\vec{n}')|}. \quad (3.7)$$

The multipole expansion in terms of site symmetry adapted functions (SAF's)²¹ is

$$V(\vec{R}(\vec{n}), \vec{R}'(\vec{n}')) = \sum_{\Lambda\Lambda'} v_{\Lambda\Lambda'}(\vec{n}, \vec{n}'; r, r') S_{\Lambda}(\hat{n}) S_{\Lambda'}(\hat{n}'), \quad (3.8)$$

where

$$v_{\Lambda\Lambda'}(\vec{n}, \vec{n}'; r, r') = \int d\Omega(\vec{n}) \int d\Omega'(\vec{n}') \frac{S_{\Lambda}(\hat{n}) S_{\Lambda'}(\hat{n}')}{|\vec{R}(\vec{n}) - \vec{R}'(\vec{n}')|}. \quad (3.9)$$

The SAF's are linear combinations of spherical harmonics and transform as irreducible representations of a site point group, Ref. 21. The index Λ stands for (l, τ) , with $\tau = (\Gamma, \mu, k)$. Here l accounts for the angular dependence of the multipolar expansion, Γ denotes an irreducible representation (in the present case the group is O_h), μ labels the representations that occur more than once and k denotes the rows of a given representation.

The intrasite case corresponds to $\vec{n} = \vec{n}'$. The interaction function $v_{\Lambda\Lambda'}(r, r') \equiv v_{\Lambda\Lambda'}(\vec{n} = \vec{n}'; r, r')$ then becomes particular simple,

$$v_{\Lambda\Lambda'}(r, r') = \left(\frac{r_{<}^l}{r_{>}^{(l+1)}} \right) \frac{4\pi}{2l+1} \delta_{\Lambda\Lambda'}, \quad (3.10)$$

where $r_{>} = \max(r, r')$, $r_{<} = \min(r, r')$ and $\delta_{\Lambda\Lambda'} = \delta_{\tau\tau'} \delta_{ll'}$. The last expression is also site independent.

There is no simple analytical expression for the intersite case, $\vec{n} \neq \vec{n}'$.⁴⁰ The intersite multipole interactions are anisotropic and for practical purposes it is important to use the following dependence⁴⁰

$$v_{\Lambda\Lambda'}(\vec{n}, \vec{n}'; r, r') \sim \frac{(r)^l (r')^{l'}}{|\vec{X}(\vec{n}) - \vec{X}(\vec{n}')|^{l+l'+1}}. \quad (3.11)$$

D. Intrasite matrix elements

For the Coulomb interaction between four electrons on a same site $\vec{n}$ we have a sum of six two-body terms,

$$V^{(4)} = \frac{1}{2} \sum_{t=1}^4 \sum_{p(\neq t)=1}^4 V(\vec{r}_t, \vec{r}_p), \quad (3.12)$$

where each term is given by the multipole expansion (3.8). In order to calculate the matrix elements of $V^{(4)}$, $\langle i_1^f, i_2^f, i_3^f; i^s | V^{(4)} | j_1^f, j_2^f, j_3^f; j^s \rangle$, one has to classify the

electronic transitions. Following Ref. 19 where the energy terms of molecular ions $C_{60}^{m\pm}$, $m = 2 - 5$, were calculated, we consider four possibilities for the fourth s -electron: (1) $i^s \rightarrow j^s$, (2) $i^s \rightarrow j_3^f$, (3) $i^s \rightarrow j_2^f$, and (4) $i^s \rightarrow j_1^f$, which we label by the index $a_4 = 1 - 4$. The $a_4 = 2$ and $a_4 = 4$ transitions involve odd number of transpositions among $j_1^f, j_2^f, j_3^f; j^s$, and the parity is $P(a_4 = 2) = P(a_4 = 4) = -1$. For two other transitions the number of transpositions is even and $P(a_4 = 1) = P(a_4 = 3) = 1$. After this we are left with only three j -states, which we label as j'_1, j'_2 , and j'_3 . For the next electron, i_3^f , we can consider three possibilities ($i_3^f \rightarrow j'_3$, $i_3^f \rightarrow j'_2$, $i_3^f \rightarrow j'_1$) which we label by the index $a_3 = 1 - 3$. In this way we continue until we exhaust all four electrons. As a result, each subcase (or electron transition) is classified by the three index label $a \equiv (a_4, a_3, a_2)$, and its parity is $P(a) = P(a_4)P(a_3)P(a_2)$. Mathematically, we reduce a permutation of four electrons to a product of transpositions. The matrix element $\langle I | V^{(4)} | J \rangle$ is found as⁴¹

$$\langle I | V^{(4)} | J \rangle = \sum_a P(a) \langle I | V^{(4)} | J \rangle^{(a)}, \quad (3.13)$$

where $\sum_a = \sum_{a_4=1}^4 \sum_{a_3=1}^3 \sum_{a_2=1}^2$, and

$$\begin{aligned} \langle I | V^{(4)} | J \rangle^{(a)} &= \sum_{l, \tau} v_l^{s, j_{a4}-f, j_{a3}} c_{l, \tau}(i^s j_{a4}) c_{l, \tau}(i_3^f j_{a3}) \\ &\times \delta(i_2^f, j_{a2}) \delta(i_1^f, j_{a1}) + p.i. \end{aligned} \quad (3.14)$$

Here *p.i.* stands for the other pair Coulomb interactions, Eq. (3.12). (The explicitly written term in Eq. (3.14) corresponds to the interaction between fourth and third electron.) The elements $c_{\Lambda}(ij) \equiv c_{l, \tau}(ij)$ are defined by

$$c_{\Lambda}(ij) = \int d\Omega \langle i | \hat{n} \rangle S_{\Lambda}(\hat{n}) \langle \hat{n} | j \rangle. \quad (3.15)$$

For the $7s5f^3$ configuration there are three types of these coefficients. For the $s - s$ transition it is only one integral $\langle s | Y_0^0 | s \rangle = 1/\sqrt{4\pi}$, which is not zero. For the $f - f$ transitions and real spherical harmonics,²¹ the coefficients $c_{l, \tau}(i^f j^f)$ were tabulated in Ref. 16. Finally, there are $f - s$ and $s - f$ transitions which require the evaluation of $c_{l, \tau}(i^f j^s)$. From the orthogonality of spherical harmonics we find that

$$\langle 0, 0 | Y_3^{\tau} | 3, \tau \rangle = \frac{1}{\sqrt{4\pi}}, \quad (3.16)$$

where $\tau = 0, (m, c), (m, s)$, $m = 1 - 3$, and zero otherwise. The matrix quantities (3.15) were first introduced by Condon and Shortley for the description of atomic spectra,²⁰ but they are also at the center of the calculation of the crystal electric field effects.¹⁶

In Eq. (3.14) $v_l^{s, j_{a4}-f, j_{a3}}$ stands for a radial average. The general expression is

$$\begin{aligned} v_l^{a, b-c, e} &= \int dr r^2 \int dr' r'^2 \mathcal{R}_a(r) \mathcal{R}_b(r) \\ &\mathcal{R}_c(r') \mathcal{R}_e(r') v_l(r, r'), \end{aligned} \quad (3.17)$$

where $\mathcal{R}_a$, $\mathcal{R}_b$, $\mathcal{R}_c$ and $\mathcal{R}_e$ are radial components, and $v_l(r, r') = v_{\Lambda\Lambda}(r, r')$ is given by Eq. (3.10). For the $7s5f^3$ configuration the indices a, b, c, e refer either to $7s$ or to $5f$ electron radial components. There are only two types of radial integrals, corresponding to nontrivial multipolar terms ($l \neq 0$) of $7s5f^3$, which are

$$v_l^{ff-ff} = \int dr r^2 \int dr' r'^2 \mathcal{R}_f^2(r) \mathcal{R}_f^2(r') v_l(r, r'), \quad (3.18a)$$

$$v_{l'}^{fs-sf} = \int dr r^2 \int dr' r'^2 \mathcal{R}_s(r) \mathcal{R}_f(r) \mathcal{R}_f(r') \mathcal{R}_s(r') v_l(r, r'). \quad (3.18b)$$

Here $l = 2, 4, 6$ and $l' = 3$, as follows from the selection rules for $c_\Lambda(ff)$ and $c_{\Lambda'}(fs)$. The radial integrals v_l^{ff-ff} and $v_{l'}^{fs-sf}$ are proportional to the quantities F_l and $G_{l'}$ introduced by Condon and Shortley in Ref. 20. It is important to notice that even the $7s$ electron with the trivial dependence of its angular part is strongly coupled to the three $5f$ electrons through $f-s$ and $s-f$ transitions.

The classification scheme for electronic transitions which we have introduced here is very useful for handling the single particle interactions as well. The main difference is that now the interaction occurs to a single electron while the rest of them produce Kronecker factors, Ref. 19. This group of interactions includes the spin-orbit coupling H_{so} , the crystal electric field V_{CF} and the mean field V_{MF} . The latter two interactions are dealt with in Secs. IV and V. The spin-orbit coupling is

$$H_{so} = \sum_i V_{so}(i), \quad (3.19)$$

where the sum runs over all electrons, V_{so} being the corresponding one-electron spin-orbit operator. The s -electron does not experience the spin-orbit coupling and in the $7s5f^3$ case the summation includes only three $5f$ terms $V_{so}(i^f)$, $i^f = 1-3$, where

$$V_{so}(i^f) = \zeta_f \vec{L}(i^f) \vec{S}(i^f). \quad (3.20)$$

Here $\vec{L}(i^f)$ and $\vec{S}(i^f)$ are the one-electron operators of orbital and spin momentum, ζ_f is the constant of the spin-orbit coupling. The full intrasite Hamiltonian is given by $H_{intra} = V^{(4)} + H_{so}$. It describes the $7s5f^3$ configuration of a free neptunium ion. Since the present method is not based on perturbation theory it extends the classical calculations of Condon and Shortley.²⁰

E. Intersite matrix elements

We start with expression (3.8) and write it in the space of many electron basis vectors $|I\rangle$, Eq. (3.2). Carrying out the angular integrations $d\Omega(\vec{n})$, $d\Omega'(\vec{n}')$, $d\Omega(\vec{n}'')$, we obtain

$d\Omega'(\vec{n}')$, we obtain

$$\begin{aligned} & \langle I | \vec{n} \langle I' | \vec{n}' V(\vec{R}(\vec{n}), \vec{R}'(\vec{n}')) | J' \rangle \vec{n}'' | J \rangle \vec{n} \rangle = \frac{1}{N_a} \\ & \times \sum_{a(\vec{n})} \sum_{a'(\vec{n}')} P(a_{\vec{n}}) P(a'_{\vec{n}'}) \sum_{\alpha=1}^4 \sum_{\alpha'=1}^4 \sum_{\Lambda\Lambda'} v_{\Lambda}^{\alpha\alpha} v_{\Lambda'}^{\alpha'\alpha'} (\vec{n} - \vec{n}') \\ & \times \left\{ c_\Lambda(i_\alpha j_\alpha^a) \prod_{\beta=1}^3 \delta(i_\beta j_\beta^a) \right\} \left\{ c_{\Lambda'}(i'_{\alpha'} j'_{\alpha'}{}^{a'}) \prod_{\beta'=1}^3 \delta(i'_{\beta'} j'_{\beta'}{}^{a'}) \right\}. \end{aligned} \quad (3.21)$$

Here the sum over a means the summation over all permutations of indices j_1^f, j_2^f, j_3^f, j^s at site $\vec{n}$ transforming them to indices j_α^a ($\alpha = 1-4$). Analogously, the sum over a' implies the summation over all permutations of $j_1'^f, j_2'^f, j_3'^f, j'^s$ at site $\vec{n}'$ transforming them to $j_{\alpha'}^{a'}$ ($\alpha' = 1-4$). $P(a)$ and $P(a')$ stand for the parities of the permutations. Indices α and α' indicate which electron at site $\vec{n}$ interacts with which electron at site $\vec{n}'$. The other electrons labeled by $\beta = 1-3$ at site $\vec{n}$ and by $\beta' = 1-3$ at site $\vec{n}'$ do not contribute to the interaction and produce the Kronecker delta symbols. The coefficients c_Λ are defined by Eq. (3.15), and the intersite ($\vec{n} \neq \vec{n}'$) interaction element $v_{\Lambda}^{\alpha\alpha} v_{\Lambda'}^{\alpha'\alpha'}$ is given by

$$\begin{aligned} v_{\Lambda}^{\alpha\alpha} v_{\Lambda'}^{\alpha'\alpha'} (\vec{n} - \vec{n}') &= \int dr r^2 \int dr' r'^2 \\ &\times \mathcal{R}_\alpha^2(r) \mathcal{R}_{\alpha'}^2(r') v_{\Lambda\Lambda'}(\vec{n}, \vec{n}'; r, r'). \end{aligned} \quad (3.22)$$

For the four electron space of $7s5f^3$ only even l and l' (in Λ, Λ') are retained in Eqs. (3.21) and (3.22), and $l, l' = 0, 2, 4, 6$. Two very important examples of intersite Coulomb interactions, namely, the crystal electric field and the mean field will be considered in sections IV and V.

IV. CRYSTAL AND MEAN FIELD OF THE $5f^3$ NEPTUNIUM CONFIGURATION

In this section we study the model where we assume that there are only three localized $5f$ electrons at each neptunium site. Although we believe that the model is not adequate for a realistic description of NpO_2 , especially in the part concerning the loss of the magnetic moments in the ordered phase, it is nevertheless very instructive to consider it in detail. The $5f^3$ configuration being relatively simple offers an opportunity to be studied thoroughly and to understand the interplay between the disordered and ordered phases, or between the crystal and quadrupolar mean field. On the other hand, the configurations $7p5f^3$ and $6d5f^3$ involve too many basis states and consume too much time to be processed self-consistently for any temperature.

A. Free ion electron energy spectrum

The basis states for the $5f^3$ configuration are given by

$$|I\rangle = |i_1^f, i_2^f, i_3^f\rangle, \quad (4.1)$$

where as before, $i^f = 1 - 14$. The total number of basis vectors is $14 \times 13 \times 12/3! = 364$. We treat the $5f^3$ configuration in the way which was specified in Sec. III.

There are only $f - f$ transitions described by four radial integrals (3.18a): v_l^{ff-ff} , $l = 0, 2, 4, 6$. The others are zero due to the selection rules imposed by the coefficients $c_\Lambda(ij)$, Eq. (3.15). The radial integral v_0^{ff-ff} (Hubbard U) is not important here since it does not result in term splittings. In the following we will use the condense notation F for ff and thus $v_l^{ff-ff} \equiv v_l^{F-F}$. These quantities are connected with the Slater (Condon-Shortley) parameters²⁰ $F^l(5f, 5f)$ through the following relation:

$$v_l^{F-F} = \frac{4\pi}{2l+1} F^l. \quad (4.2)$$

In particular, the Slater parameters F^2 , F^4 , and F^6 of Amoretti *et al.*⁴² correspond to $v_2^{F-F} = 14.007$ eV, $v_4^{F-F} = 7.091$ eV and $v_6^{F-F} = 3.168$ eV. (In order to obtain the exact term splitting quoted in Table IV of Ref. 42 we had to scale their Slater parameters by a factor 0.9755.) Alternatively, the quantities v_l^{F-F} can be calculated by using the radial dependence of the $5f$ electrons $\mathcal{R}_f$, Eq. (3.18a). We have done such a calculation and then corrected the parameters by comparing the splittings of the f^3 configuration with experimental data for Pr^{3+} and Nd^{4+} (details are given in Appendix B). We arrived at

$$\begin{aligned} v_2^{F-F} &= 18.164, & v_4^{F-F} &= 8.578, & v_6^{F-F} &= 3.362, \\ \zeta_f &= 0.2547, & \text{in eV.} \end{aligned} \quad (4.3)$$

After calculating the matrix elements of the Coulomb repulsion and the spin-orbit coupling, we diagonalize the matrix

$$H_{\text{intra}} = V^{(3)} + H_{so} \quad (4.4)$$

and obtain the electronic spectrum of $5f^3$. The 9 lowest and two highest eigenvalues are shown in Table IV, where for comparison we also quote the spectrum of free Np ion of Ref. 42. Notice, that in comparison with the spectrum⁴² of Amoretti *at al.*, $^4F_{3/2}$ and $^4F_{5/2}$ are higher than $^4I_{13/2}$ and $^2H_{9/2}$, which is in better agreement with the sequence of terms for the $4f^3$ configurations of Pr^{3+} and Nd^{4+} known from experiment.⁴³

B. CEF excitations in the disordered phase ($T > 25$ K)

In the disordered phase ($T > 25$ K) the electron density of the $5f^3$ configuration adopts the cubic (O_h) site

TABLE IV: The 9 lowest and 2 highest eigenvalues of $5f^3$, calculated with v_l^{F-F} , Eq. (4.3). g stands for the Landé factor. E^A refers to the calculation of Amoretti *et al.*, Ref. 42. Two highest values of E^A marked by an asterisk were reproduced by our calculation with the parameters of Ref. 42.

symmetry. This density modulation is induced by the cubic crystal electric field experienced by three $5f$ electrons. In terms of the multipole intersite expansion (3.8) it implies that for a given Np site $\vec{n}$ we treat 12 Np neighbors ($\vec{n}'_1 = 1 - 12$) and 8 oxygen neighbors ($\vec{n}'_2 = 1 - 8$) in spherical approximation, i.e. $l' = 0$ and $S_{\Lambda'}(\vec{n}')$ reduces to $Y_0^0 = 1/\sqrt{4\pi}$. The coefficients $c_{\Lambda'}$, Eq. (3.15), become simple,

$$c_0(i_{\alpha'} j_{\alpha'}) = \frac{1}{\sqrt{4\pi}} \delta(i_{\alpha'}, j_{\alpha'}). \quad (4.5)$$

Here we write 0 for $\Lambda' \equiv (l' = 0, A_{1g})$. At the central site $\vec{n}$ we expand the CEF in terms of SAF's $S_{\Lambda_1}(\vec{n})$, $\Lambda_1 \equiv (l, A_{1g})$, where A_{1g} stands for the unit representation of the cubic site group O_h . The selection rules for the coefficients $c_\Lambda(i_\alpha, j_\alpha)$ of the $f - f$ transitions imply that there remain only two nontrivial functions S_{Λ_1} with $l = 4$ and $l = 6$, which correspond to the cubic harmonics $K_4(\Omega)$ and $K_6(\Omega)$. The multipole two-center expansion (3.8) becomes

$$V(\vec{R}(\vec{n}), \vec{R}'(\vec{n}')) = \frac{1}{\sqrt{4\pi}} \sum_{\Lambda_1} v_{\Lambda_1 0}(\vec{n}, \vec{n}'; r, r') S_{\Lambda_1}(\vec{n}), \quad (4.6a)$$

where

$$v_{\Lambda_1 0}(\vec{n}, \vec{n}'; r, r') = \frac{1}{\sqrt{4\pi}} \int d\Omega(\vec{n}) \int d\Omega'(\vec{n}') \frac{S_{\Lambda_1}(\hat{n})}{|\vec{R}(\vec{n}) - \vec{R}'(\vec{n}')|}. \quad (4.6b)$$

Here $v_{\Lambda_1 0}(\vec{n}, \vec{n}'; r, r')$ has a same value for all 12 Np neighbors ($\vec{n}'_1 = 1 - 12$), and a same value for all 8 oxygen neighbors ($\vec{n}'_2 = 1 - 8$). As follows from Eq. (3.11) $v_{\Lambda_1 0}(\vec{n}, \vec{n}'; r, r')$ is independent of r' . Eq. (3.22) then can be written in the following form:

$$v_{\Lambda_1 0}^{\alpha\alpha' \alpha'\alpha'}(\vec{n} - \vec{n}') = v_{\Lambda_1 0}^{\alpha\alpha} \cdot Q_{\alpha'}, \quad (4.7)$$

where

$$v_{\Lambda_1 0}^{\alpha\alpha} = \int dr r^2 \mathcal{R}_\alpha^2(r) v_{\Lambda_1 0}(\vec{n}, \vec{n}'; r, \not{r}') \quad (4.8a)$$

and

$$Q_{\alpha'} = \int dr' r'^2 \mathcal{R}_{\alpha'}^2(r'). \quad (4.8b)$$

Here the integrations are taken over $0 < r' < R_{MT}$, where R_{MT} is the radius of the muffin-tin sphere of neptunium or oxygen. (The influence of the interstitial region will be discussed later.) $Q_{\alpha'}$ refers to an electron at site $\vec{n}'$ which interacts with one of the three $5f$ electrons at $\vec{n}$. We then can perform a summation over all electrons at $\vec{n}'$ and include also to this term the interaction with the nucleus. This results in replacing $Q_{\alpha'}$ by eQ_{MT} in Eq. (4.7), Q_{MT} and e being the total charge inside the MT sphere and the electron charge ($e = -1$), respectively. From Eq. (3.11) it follows that

$$v_{\Lambda_1 0}^{\alpha\alpha} = v_{\Lambda_1 0}(\vec{n}, \vec{n}'; R_{MT}, \not{r}') \frac{q_l^\alpha}{R_{MT}^l}, \quad (4.9a)$$

where l in the index Λ_1 is 4 or 6, and

$$q_l^\alpha = \int dr' r'^{(l+2)} \mathcal{R}_\alpha^2(r'). \quad (4.9b)$$

Therefore, the CEF operator for any neptunium site ($r < R_{MT}^{Np}$) can be written explicitly as

$$V_{CF}(\vec{R}(\vec{n})) = \sum_{l=4,6} B_l S_{(l, A_{1g})}(\hat{n}) \left(\frac{r}{R_{MT}^{Np}} \right)^l, \quad (4.10a)$$

where

$$B_l = B_l^{Np} + B_l^O, \quad (4.10b)$$

and

$$B_l^{Np} = \frac{12}{\sqrt{4\pi}} Q_{eff}^{Np} e v_{\Lambda_1 0}(\vec{n}, \vec{n}_1'; R_{MT}^{Np}, \not{r}'), \quad (4.10c)$$

$$B_l^O = \frac{8}{\sqrt{4\pi}} Q_{eff}^O e v_{\Lambda_1 0}(\vec{n}, \vec{n}_2'; R_{MT}^{Np}, \not{r}'). \quad (4.10d)$$

We quote all relevant parameters of CEF in Table V. As given by Eq. (4.10a), the CEF operator V_{CF} is a one-electron quantity.^{44,45} CEF acts along with the Coulomb intrasite repulsion, Eq. (4.4). Therefore, the total Hamiltonian for the disordered phase becomes

$$H^{dis}(\vec{n}) = H_{intra} + V_{CF}(\vec{n}). \quad (4.11)$$

Although we have considered CEF from first principles there is still an ambiguity related to the charge distribution in the interstitial region. A more rigorous treatment of the problem is given in Refs. 46,47. A careful consideration of the problem based on the solution of a periodic Poisson's equation leads to a renormalization of the

TABLE V: Calculated parameters of the CEF. $v_{\Lambda_1 0}^{Np Np} = v_{\Lambda_1 0}(\vec{n}, \vec{n}_1'; R_{MT}^{Np}, \not{r}')$, $\vec{n} = 0$ is the central Np site, $\vec{n}_1'$ is one of 12 Np nearest neighbors. $v_{\Lambda_1 0}^{Np O} = v_{\Lambda_1 0}(\vec{n}, \vec{n}_2'; R_{MT}^{Np}, \not{r}')$, $\vec{n}_2'$ is one of 6 oxygen neighbors.

charges inside the MT spheres, Ref. 47. In other words, in Eqs. (4.10a-d) the effective charges for Np and O are given by

$$Q_{eff} = Q_{MT} - \frac{4\pi R_{MT}^3}{3} \rho_I(\vec{K} = 0) - 4\pi R_{MT}^2 \sum_{\vec{K} \neq 0} \frac{j_1(K R_{MT})}{K} \rho_I(\vec{K}), \quad (4.12)$$

where $\rho_I(\vec{K})$ is the Fourier series expansion of the electron density in the interstitial region, $j_{l=1}$ is the spherical Bessel function. $\rho_I(\vec{K} = 0)$ is the average density in the interstitial region, Q_{out}/V_{out} , where Q_{out} and V_{out} is the charge and volume of the interstitial region.

The calculation of Q_{eff} according to Eq. (4.12) is quite laborious since it requires the evaluation of the Fourier coefficients $\rho_I(\vec{K})$. Instead, below we consider two approximation to (4.12). In the first approximation we assume that $Q_{eff}^{Np}(I) = Q_{MT}^{Np}$ and $Q_{eff}^O(I) = Q_{MT}^O$, where Q_{MT}^{Np} and Q_{MT}^O are the total charges inside the MT spheres of neptunium and oxygen. Here the electron charge in the interstices is completely ignored. In the second approximation we take

$$Q_{eff}(II) = Q_{MT} - \frac{4\pi R_{MT}^3}{3} \rho_I(\vec{K} = 0). \quad (4.13)$$

This expression corresponds to the homogeneous electron density distribution in the interstitial region. However, the modification of effective charges in this approximation is too strong: $Q_{eff}^{Np}(I) = +4.108|e|$ and $Q_{eff}^{Np}(II) = +5.337|e|$ for neptunium, $Q_{eff}^O(I) = -0.284|e|$ and $Q_{eff}^O(II) = +0.945|e|$ for oxygen. As was discussed in Refs. 18,48 the CEF splitting is overestimated in the second approximation. In reality the charge density in interstices is highly inhomogeneous, concentrated mainly in the proximity to oxygen and neptunium. This leads to $\rho_I(\vec{K} \neq 0) \neq 0$, and the last term in Eq. (4.12) acts in the opposite direction, decreasing Q_{eff} backward to Q_{MT} values, which correspond to the first approximation.

The exact calculation of Q_{eff} according to Eq. (4.12) is beyond the scope of the present study. Instead, we have

FIG. 2: Splitting of the lowest $^4I_{9/2}$ terms of the $5f^3$ configuration of Np in cubic crystal field, Eqs. (4.10a-d) as a function of the effective charges of neptunium and oxygen, Eq. (4.14a,b). Zero corresponds to the energy of the $^4I_{9/2}$ level of free Np ion.

studied the crystal field effects as a function of Q_{eff} by introducing

$$Q_{eff}^{Np}(x_{eff}) = Q_{MT}^{Np} + x_{eff}(Q_{eff}^{Np}(II) - Q_{MT}^{Np}), \quad (4.14a)$$

$$Q_{eff}^O(x_{eff}) = Q_{MT}^O + x_{eff}(Q_{eff}^O(II) - Q_{MT}^O), \quad (4.14b)$$

where $0 < x_{eff} < 1$. Diagonalizing H^{dis} , Eq. (4.11), we have found that 41 terms of $5f^3$ are split into 120 distinct sublevels of Γ_6 , Γ_7 and Γ_8 symmetry of the cubic double group O'_h . In particular two lowest atomic-like levels are split according to the following scheme,

$$^4I_{9/2} \rightarrow \Gamma_8 + \Gamma_8 + \Gamma_6, \quad (4.15a)$$

$$^4I_{11/2} \rightarrow \Gamma_8 + \Gamma_7 + \Gamma_6 + \Gamma_8. \quad (4.15b)$$

The resulting splittings and the dependence of CEF on x_{eff} is shown in Fig. 2. The splittings of two lowest terms of the $5f^3$ configuration, Eq. (4.15a,b), is also given in Tables VI and VII for $x_{eff} = 0$ and $x_{eff} = 0.5$, respectively.

The most comprehensive study of the crystal field of the $5f^3$ configuration was performed by Amoretti *et al.*, Ref. 42. Comparing their results with ours, we obtain the following relations connecting B_4 and B_6 with V_4 and V_6 used there,

$$B_4 = 8\sqrt{\frac{12}{7}}V_4, \quad (4.16a)$$

$$B_6 = 16\sqrt{8}V_6. \quad (4.16b)$$

We observe that for a realistic choice of Q_{eff} , which corresponds to $x_{eff} \sim 0 - 0.5$, the CEF splitting is a *few times smaller* than the value 55 meV considered for CEF excitations in Ref. 42. Correspondingly, the calculated

parameters B_4 and B_6 (Tables VI and VII) are smaller. We discuss a possible explanation to this fact in the Conclusions, Sec. VI. Notice that it is not possible to relate the feature at 55 meV with the $^4I_{11/2}$ splittings because it is situated at much higher energy ~ 650 meV, Table IV. Most likely, the experimental excitations at 55 meV refer to the valence electrons delocalized on the Np-O bonds, while the lowest CEF excitations of Np lie at a smaller energy ~ 6 meV, Tables VI, VII.

Finally, we would like to notice that our CEF calculation is based on first principles, and in that respect it differs from the others,^{42,49,50} which use fitting from experiment to extract the CEF parameters. There are also other technical differences. In contrast to Refs. 49,50 we do not assume that the full momentum J is a good quantum number, that allows for a mixing of components belonging to different J . In Ref. 42 the basis was truncated to the first 11 low-lying levels. In our approach we do not have these limitations.

C. Mean field and the structural phase transition at 25 K

Now we consider the intersite quadrupole interactions $V^{QQ}(\vec{n}, \vec{n}')$ between a central Np site (sublattice $\{n_1\}$) and its 12 nearest Np neighbors belonging to sublattices $\{n_{p'}\}$, $p' = 2, 3, 4$. (Here we will not take into account the interactions involving higher spherical harmonics because

they are considerably smaller, Eq. (3.11).) We will handle the $Pn\bar{3}m$ and $Pa\bar{3}$ symmetries together since both of them result in the same local quadrupolar function (2.1a) for neptunium.

The problem for the $Pa\bar{3}$ structure has been considered in Refs. 16,18 where it is shown that this spatial order of quadrupoles gives an effective attraction between them. This direct quadrupole-quadrupole coupling can be calculated from first principles. However, we will see that its strength is not sufficient and we have to assume a substantial reinforcement via oxygen mediated interaction. For the $Pn\bar{3}m$ structure the direct interaction is repulsive and we have to resort to the indirect coupling from the very beginning. The important fact which we exploit in this section is that *the rhombohedral (trigonal) mean field for both structures can be described by the same expression* (4.22) below.

We start by deriving an effective mean field for direct Coulomb coupling between quadrupoles in the $Pa\bar{3}$ structure. Following Ref. 18, one obtains from Eq. (3.21) the following expression for the quadrupolar interaction operator between neptunium sites at $\vec{n}_1$ and $\vec{n}_{p'}$

$$V^{QQ}(\vec{n}_1, \vec{n}_{p'}) = -\frac{\gamma^{ff}}{3} \rho_f^Q(\vec{n}_1) \rho_f^Q(\vec{n}_{p'}). \quad (4.17)$$

Here $\vec{n}_1 \in \{n_1\}$, $\vec{n}_{p'} \in \{n_{p'}\}$, and the quadrupolar density operator ρ_f^Q at site $\vec{n}_p$ is given by

$$\rho_f^Q(\vec{n}) = \sum_{I,J} |I\rangle \sum_a P(a) \sum_{\alpha=1}^3 c_p(i_\alpha j_\alpha^a) \prod_{\beta=1}^2 \delta_{i_\beta j_\beta^a} \langle J|, \quad (4.18)$$

where again a is a permutation of j_1^f, j_2^f, j_3^f transforming them to a new order given by j_κ^a , $\kappa = 1 - 3$. $P(a)$ is the parity of the permutation, the index α stands for the interacting electron at the site. (The second interacting electron belongs to a neighboring Np site.) The other (noninteracting) electrons ($\beta = 1, 2$) at $\vec{n}$ produce the product of the Kronecker delta symbols. The quadrupolar $f-f$ coefficients are defined as

$$c_p(i_\alpha j_\alpha) = \langle i_\alpha | \mathcal{S}_p | j_\alpha \rangle. \quad (4.19)$$

There are four types of such coefficients (i.e. $p = 1 - 4$) as follows from Eqs. (2.1a-d). Finally, the interaction constant γ^{ff} in Eq. (4.17) is given by

$$\gamma^{ff} = \int dr r^2 \int dr' r'^2 \mathcal{R}_f^2(r) \mathcal{R}_f^2(r') v_{\Lambda\Lambda}(\vec{n}, \vec{n}'; r, r'), \quad (4.20)$$

with $v_{\Lambda\Lambda}(\vec{n}, \vec{n}'; r, r')$ defined by Eq. (3.9), where $\vec{n} = (0, 0, 0)$, $\vec{n}' = (a/2)(0, 1, 1)$ and $\Lambda = (l = 2, T_{2g}, k = 1)$. The corresponding SAF is $S_\Lambda = Y_2^{1s}$. Using the property (3.11) we rewrite γ^{ff} as

$$\gamma^{ff} = \frac{q_2^f}{(R_{MT}^{Np})^2} v^{QQ}(R_{MT}^{Np}) \frac{q_2^f}{(R_{MT}^{Np})^2}, \quad (4.21)$$

TABLE VIII: Calculated parameters of the mean field.

$v^{QQ}(R_{MT}^{Np})$	$q_2^f / (R_{MT}^{Np})^2$	γ^{ff}	λ^{ff}
4568.2 K	0.3095	437.6 K	1750.5 K

where the short notation $v^{QQ}(R_{MT}^{Np})$ stands for $v_{\Lambda\Lambda}(\vec{n}, \vec{n}'; R_{MT}^{Np}, R_{MT}^{Np})$, and the “quadrupole charge” $q_{l=2}^f$ of 5f electron is given by Eq. (4.9b).

In the mean-field approximation after summing over 12 nearest neighbors belonging to 3 sublattices we arrive at the effective bilinear quadrupole-quadrupole operator

$$U^{QQ}(\vec{n}_p) = -\lambda^{ff} \langle \rho_f^Q \rangle \rho_f^Q(\vec{n}_p), \quad (4.22)$$

where $\lambda^{ff} = 4\gamma^{ff} > 0$ and the calculated parameters are quoted in Table VIII. The same expression holds for $Pn\bar{3}m$, but in that case for the direct quadrupole interaction $\lambda^{ff} < 0$ (repulsion), Appendix A. $\langle \rho_f^Q \rangle$ stands for an expectation value of the quadrupole operator (4.18). At zero temperature it is the quantum average

$$\langle \rho_f^Q \rangle = \langle I_{gs} | \rho_f^Q(\vec{n}_p) | I_{gs} \rangle, \quad (4.23)$$

where $|I_{gs}\rangle$ refers to the ground state of the full mean-field Hamiltonian

$$H^{MF}(\vec{n}) = U^{QQ}(\vec{n}) + V_{CF}(\vec{n}) + H_{intra}(\vec{n}). \quad (4.24)$$

The intrasite part of the interactions H_{intra} is given by Eq. (4.4). For CEF we used the values $x_{eff} = 0$ and $Q_{eff}^{Np} = Q_{MT}^{Np}$, $Q_{eff}^O = Q_{MT}^O$. (As we discussed in Sec. IV.B this gives the most realistic estimate for CEF.) For both $Pa\bar{3}$ and $Pm\bar{3}n$ structures the mean-field Hamiltonian has the $S_6 = C_3 \times i$ trigonal common site symmetry, and lifts the 4-fold degeneracy of the quartet states,

$$\Gamma_8 \rightarrow E + E, \quad (4.25)$$

where E stands for the two-fold degenerate irreducible representation of C_3 . The states Γ_6 remain unsplit as a consequence of the Kramers theorem, $\Gamma_6 \rightarrow E$.

We now obtain a system of equations which can be solved self-consistently. At first we introduce an average $\langle \rho_f^Q \rangle$, which defines the interactions (4.22), (4.24). In the space of the $5f^3$ configuration (364 state vectors), we diagonalize the total Hamiltonian H^{MF} , Eq. (4.24), and obtain the eigenvectors $|K\rangle$, $K = 1 - 364$:

$$H^{MF}|K\rangle = \epsilon_K|K\rangle, \quad (4.26)$$

where the lowest value of ϵ_K corresponds to $K = 1, 2$. This is the Kramers doublet of the ground state. We then calculate the quantities

$$\rho_f^Q(K) = \langle K | \rho_f^Q(\vec{n}_p) | K \rangle, \quad (4.27)$$

which evaluate the quadrupolar moments of the states K . Next, we find an improved value for $\langle \rho_f^Q \rangle$ which is

FIG. 3: A typical evolution of the order parameter amplitude $\langle \rho_f^Q \rangle$ with temperature; $\rho_0 = \langle \rho_f^Q \rangle|_{T=0}$, T_Q is the transition temperature.

TABLE IX: Mean-field (trigonal) splittings at $T = 0$, $\lambda_{eff}/\lambda^{ff} = 1$. $T_Q = 0.44$ K, $\rho_0 = -0.0205$.

Γ	deg.	$(\epsilon_i - \epsilon_1)$ (K)	$\mathcal{M}_z(\mu_B)$	ρ_f^Q
E	2	0	± 0.9464	-0.0205
E	2	1.1	± 0.7962	0.0135
E	2	20.7	± 0.6406	-0.0083
E	2	21.7	± 0.8428	0.0140
E	2	60.8	± 1.3840	0.0011

$\rho_f^Q(K=1) = \rho_f^Q(K=2)$, Eq. (4.23). The procedure continues until the input and output values for $\langle \rho_f^Q \rangle$ converge. As a consequence of symmetry the expectation value $\langle \rho_f^Q \rangle$ is independent of the sublattice $\{n_p\}$ chosen for calculations, but the Hamiltonian and eigenvectors do depend on the choice. This is because the quadrupoles have different orientations for different sublattices.

For nonzero temperature T the mean-field equation for $\langle \rho_f^Q \rangle$ becomes

$$\langle \rho_f^Q \rangle = \frac{1}{Z} \sum_K \rho_f^Q(K) e^{-\epsilon_K/T}, \quad (4.28a)$$

where

$$Z = \sum_K e^{-\epsilon_K/T}. \quad (4.28b)$$

The results of the calculations are quoted in Tables IX, X, and in Figs. 3, 4, 5. With $\lambda^{ff} = 1750.5$ K, Table VIII, which corresponds to the direct quadrupole-quadrupole attraction of the $Pa\bar{3}$ structure, we found that the transition temperature T_Q is only 0.44 K. A typical dependence of $\langle \rho_f^Q \rangle$ is shown in Fig. 3. The phase transition is of first order, with a discontinuity of the order parameter amplitude $\langle \rho_f^Q \rangle = -0.0075$ at T_Q . Comparing the present calculation with that for cerium,¹⁸ we observe that the

FIG. 4: The transition temperature T_Q as a function of the quadrupolar interaction constant λ_{eff} .

TABLE X: Mean-field (trigonal) splittings at $T = 0$ with an enhanced quadrupolar interaction constant $\lambda_{eff}/\lambda^{ff} = 10$. $T_Q = 24.6$ K, $\rho_0 = -0.0563$.

Γ	deg.	$(\epsilon_i - \epsilon_1)$ (K)	$\mathcal{M}_z(\mu_B)$	ρ_f^Q
E	2	0	± 1.9211	-0.0563
E	2	54.0	± 1.1723	-0.0014
E	2	72.8	± 1.3684	-0.0004
E	2	85.8	± 0.6211	0.0249
E	2	122.1	± 1.4893	0.0256

low value of T_Q is due to a small quadrupolar susceptibility of the ground state quartet Γ_8 , since the difference in λ is not that much (for cerium $\lambda^{ff} = 2241$ K.)

The calculated transition temperature is very small in comparison with the experimental value of 25 K. We then conclude that in the framework of the $5f^3$ model the structural phase transition can not be explained by means of the direct bilinear quadrupole coupling. Most likely, there is indirect coupling between $5f$ electron densities on neptunium via the oxygen atoms (superexchange interaction³²). The microscopic consideration of the superexchange interaction is beyond the scope of the present work. Instead, we model it by increasing the value of λ^{ff} . In such a case λ^{ff} becomes a phenomenological parameter which we denote as λ_{eff} . By changing λ_{eff} we change the transition temperature as shown in Fig. 4. We have found that the experimental value of 25 K is achieved for $\lambda_{eff}/\lambda^{ff} \sim 10$, which indicates a substantial increase of the effective bilinear coupling, Eq. (4.22). The relevant parameters of such strong mean-field are given in Table X.

Finally, we would like to mention that the mean-field calculations have been done assuming that the CEF is weak, i.e. $x_{eff} = 0$. Increasing x_{eff} leads to an increase of the CEF splittings, which results in a strong suppression of the transition temperature T_Q , Fig. 5. Notice that at $x_{eff}(\Gamma_8 \rightarrow \Gamma_6) = 0.241$ the ground state changes to the Γ_6 doublet, Fig. 2, which is apparently unfavorable

FIG. 5: The suppression of the transition temperature T_Q with the increase of the CEF strength, x_{eff} , see also Fig. 2 and Sec. IV.B; $\lambda_{eff}/\lambda^f = 10$.

for the quadrupolar order. With further increase of x_{eff} beyond the $x_{eff}(\Gamma_8 \rightarrow \Gamma_6)$ point the transition temperature goes fast to zero and the ordered phase disappears.

V. FOUR ELECTRON CONFIGURATIONS AT NEPTUNIUM SITE

As follows from the previous section the model which takes into account only the $5f^3$ configuration at each neptunium site is not capable to explain the disappearance of the magnetic moments in the ordered phase. On the other hand, the charge distribution inside the MT sphere centered at the neptunium nucleus indicates that there is always approximately one valence electron instantaneously present along with the three localized $5f$ electrons, Table III. Even if the electron is in the s -orbital state, it experiences strong coupling with the $5f$ electrons via intrasite $s - f$ transitions. Therefore, the excitation spectrum at each neptunium site differs from that for $5f^3$ considered in Sec. IV. In the following we model the couplings with the valence electron by considering $7s5f^3$, $7p5f^3$, and $6d5f^3$ instantaneous configurations. Here we will not study the mean-field in such detail as for the $5f^3$ configuration. Our main objective is to show that the ground state can be nonmagnetic and separated from the magnetic excitations by an energy gap larger than 25 K.

A. $7s5f^3$ configuration

The $7s5f^3$ configuration has been considered in detail in Sec. III. We are working here in the space of 728 state vectors $|I\rangle = |i_1^f, i_2^f, i_3^f; i^s\rangle$. The $5f$ -states are coupled to two s -states through the $f - s$ transitions accompanied by the multipole Coulomb interactions with $l = 3$. The strength of this interaction was estimated from the LDA calculation of a Np atom, Eq. (3.18b),

$$v_3^{fs-sf} = 1.313 \text{ eV}. \quad (5.1)$$

TABLE XI: The 5 lowest and the highest eigenvalue of $7s5f^3$; g is the Landé factor.

	term	deg.	g (μ_B)	E

...	...	...	...	...
82	$^1F_0$	7	1.0172	8229.5

TABLE XII: CEF low energy spectrum and magnetic moments of the $7s5f^3$ configuration of Np, $\Delta\epsilon = 2293.2$ K. CEF parameters $B_4 = -288.1$ K, $B_6 = 254.2$ K; $x_{eff} = 0$.

	Γ	deg.	$(\epsilon_i - \epsilon_1)$ (K)	$\mathcal{M}_z(\mu_B)$
$^5I_4$	E	2	0	0; 0
	T_2	3	15.6	± 1.5671 ; 0
	T_1	3	25.1	± 0.2946 ; 0
	A	1	61.6	0
$^5I_5$	T_1	3	$\Delta\epsilon$	± 2.2435 ; 0
	E	2	$\Delta\epsilon + 4.1$	0; 0
	T_2	3	$\Delta\epsilon + 6.5$	± 2.2393 ; 0
	T_1	3	$\Delta\epsilon + 20.3$	± 2.7113 ; 0

The electron energy spectrum of the $7s5f^3$ configuration consists of 82 distinct levels, see Table XI. In the cubic crystal field two lowest levels ($^5I_4$ and $^5I_5$) are split as quoted in Table XII. Notice that the ground state is nonmagnetic. However, at higher temperatures ($T > 25$ K) two low lying excitations of T_2 and T_1 symmetry contribute to the Curie law for the magnetic susceptibility.⁶

In the ordered phase the local symmetry of the Np site changes to S_6 ($Pa\bar{3}$) or D_{3d} ($Pn\bar{3}m$). As we discussed in Sec. IV.C the mean-field can be expanded in a multipole series and from symmetry it follows that the strongest interaction is of quadrupolar type,

$$U^{QQ}(\vec{n}_p) = -\Lambda^f \rho_f^Q(\vec{n}_p), \quad (5.2)$$

where $\Lambda^f = \lambda^f f \langle \rho_f^Q \rangle$ [compare with Eq. (4.22)]. The quadrupolar operator $\rho_f^Q(\vec{n}_p)$ belonging to the sublattice $\{n_p\}$ is given again by Eq. (4.18) with the corresponding orientational function $\mathcal{S}_p$, Eqs (2.1a-d). The only difference is that the s -electron produces an additional Kronecker symbol, i.e. in Eq. (4.18) $\beta = 1 - 3$. Notice that both CEF, Eq. (4.10a), and the mean field, Eq. (5.2), act only on the $5f$ electrons. Taking $\Lambda^f = 5252$ K we diagonalized the full Hamiltonian

$$H^{MF}(\vec{n}) = U^{QQ}(\vec{n}) + V_{CF}(\vec{n}) + H_{intra}(\vec{n}). \quad (5.3)$$

The resultant electronic spectrum is shown in Table XIII. We observe that the ground state is nonmagnetic, while the first magnetic excitation (E) does not contribute to the magnetic susceptibility if $T < 25$ K.

TABLE XIII: Mean-field (trigonal) splittings of $7s5f^3$ at $T = 0$, $\Lambda^f = 5252$ K.

B. $7p5f^3$ configuration

In case of the $7p5f^3$ configuration, we construct $(14 \times 13 \times 12/3!) \times 6 = 2184$ basis vectors

$$|I\rangle = |i_1^f, i_2^f, i_3^f; i^p\rangle. \quad (5.4)$$

As before, i^f refers to a $5f$ electron, $i^p = (k, s_z)$ to the $7p$ electron (k is its orbital part, $k = 1 - 3$, and s_z is the spin part).

The interaction between $5f$ electrons was described in detail earlier. In addition, $p-p$ and $f-f$ transitions lead to intrasite multipole interactions with the $l = 0$ and $l = 2$ components, $f-p$ transitions give the Coulomb multipole couplings with $l = 2$ and $l = 4$. The relevant Slater parameters were extracted from the radial dependences of a Np ion,

$$\begin{aligned} v_2^{fp} &= 1.442, & v_4^{fp} &= 0.739, \\ v_2^{ff-pp} &= 5.237 \text{ (in eV)}. \end{aligned} \quad (5.5)$$

Also, the p -electron experiences the spin-orbit interaction with $\zeta_p = 1.2795$ eV.

First, we calculated the electron spectrum of the free ion, H_{intra} and obtained 242 distinct levels, Table XIV. In the cubic crystal the ${}^5K_4$ and ${}^5I_4$ levels are split as quoted in Table XV. (The procedure of treating CEF effects is outlined in Sec. IV.B, CEF does not act on the p -electron.) Notice, that the ground state now is a magnetic triplet of the T_2 symmetry, which together with two other magnetic T_1 excitations, Table XV, gives the Curie law for the magnetic susceptibility.

At $T_c = 25$ K the structural phase transition occurs and the symmetry of the Np sites is reduced. This symmetry change is accompanied by lifting degeneracies of

TABLE XV: CEF low energy spectrum and magnetic moments of the $7p5f^3$ configuration of Np, $\Delta\epsilon = 1789.1$ K. CEF parameters $B_4 = -288.1$ K, $B_6 = 254.2$ K; $x_{eff} = 0$.

	Γ	deg.	$(\epsilon_i - \epsilon_1)$ (K)	$\mathcal{M}_z(\mu_B)$
${}^5K_5$	T_2	3	0	$\pm 1.8525; 0$

	T_1	3	$\Delta\epsilon + 24.8$	$\pm 0.3655; 0$
	A	1	$\Delta\epsilon + 59.1$	0

TABLE XVI: Mean-field (trigonal) splittings of $7p5f^3$ at $T = 0$; $\Lambda^f = 6612$ K, $\Lambda^p = 3426$ K.

Γ	deg.	$(\epsilon_i - \epsilon_1)$ (K)	$\mathcal{M}_z(\mu_B)$
A	1	0	0
E	2	24.6	± 0.4171
E	2	105.8	± 0.8134
A	1	246.4	0
A	1	272.6	0
E	2	480.7	± 1.7473

some cubic levels. In particular, the ground state T_2 triplet is split in a doublet and a single level as demonstrated in Table XVI. The mean-field is approximated by its quadrupolar electric part,

$$U^{QQ}(\vec{n}_i) = -\Lambda^f \rho_f^Q(\vec{n}_i) - \Lambda^p \rho_p^Q(\vec{n}_i), \quad (5.6)$$

where

$$\Lambda^f = \lambda^{ff} \langle \rho_f^Q \rangle + \lambda^{fp} \langle \rho_p^Q \rangle, \quad (5.7a)$$

$$\Lambda^p = \lambda^{pf} \langle \rho_f^Q \rangle + \lambda^{pp} \langle \rho_p^Q \rangle. \quad (5.7b)$$

The following parameters of the interaction were assumed,

$$\frac{q_2^p}{(R_{MT}^{Np})^2} = 0.1604, \quad \Lambda^f = 6612 \text{ K}, \quad \Lambda^p = 3426 \text{ K}. \quad (5.8)$$

Since the charge density expansion of the p -electron has quadrupolar components, $c_k(i^p j^p) = \langle i^p | \mathcal{S}_k | j^p \rangle \neq 0$ ($\mathcal{S}_k$ are given by Eqs (2.1a-d)), the mean-field expansion (5.6) includes the quadrupolar projection on p -states,

$$\rho_p^Q(\vec{n}_k) = \sum_{I,J} |I\rangle \sum_a P(a) c_k(i^p j^p) \prod_{\beta=1}^3 \delta_{i_{\beta}^f j_{\beta}^f a_{\beta}^f} \langle J|. \quad (5.9)$$

Here a is a permutation of j_1^f, j_2^f, j_3^f to j_{β}^{af} , $\beta = 1 - 3$; $P(a)$ is the parity of the permutation. The quadrupolar operator for the $5f$ electrons is given again by Eq. (4.18)

TABLE XVII: The 5 lowest and the highest eigenvalue of $6d5f^3$; g is the Landé factor.

	term	deg.	g (μ_B)	E
1	$^5L_6$	13	0.7530	0
2	$^5K_5$	11	0.7201	167.2
3	$^5L_7$	15	0.9232	667.9
4	$^5K_6$	13	0.9269	767.2
5	$^3D_3$	7	0.6800	886.9
...	...	...	...	...
383	$^3P_1$	3	1.0004	13116.4

where the index β comprises the additional p -electron, i.e. $\beta = 1 - 3$.

Notice that in the ordered phase the ground state level is single and nonmagnetic, Table XVI. This mechanism can explain the loss of magnetic moments because the magnetic excitations of the $7p5f^3$ configuration lie too high in energy.

C. $6d5f^3$ configuration

The basis vectors here are

$$|I\rangle = |i_1^f, i_2^f, i_3^f; i^d\rangle, \quad (5.10)$$

where index i^f stands for $5f$ states ($i^f = 1 - 14$), while the index $i^d = (k, s_z)$ refers to five d -orbitals and the spin projection s_z . Thus, $i^d = 1 - 10$, and in total there are 3640 nonequivalent basis vectors $|I\rangle$.

We start by considering the intrasite interactions H_{intra} . Here, in addition to $f-f$ interactions we distinguish two groups. The first group arises between $d-d$ and $f-f$ transitions. It is described by the multipole Coulomb repulsion with the $l = 0, 2$ and 4 angular components (SAF's). The second group is due to the $f-d$ and $d-f$ transitions. The corresponding multipole interactions are with $l = 1, 3$ and 5 . The relevant parameters were extracted from the LDA calculation of the Np ion in the $6d5f^3$ configuration,

$$\begin{aligned} v_1^{fd-df} &= 11.322, & v_3^{fd-df} &= 3.701, & v_5^{fd-df} &= 1.794, \\ v_2^{ff-dd} &= 11.289, & v_4^{ff-dd} &= 3.482 & (\text{in eV}), \\ \zeta_d &= 0.3497 \text{ eV}. \end{aligned} \quad (5.11)$$

The parameters for the $f-f$ interactions were kept unchanged. We then diagonalized the 3640×3640 matrix of $\langle I | H_{intra} | J \rangle$ and obtained 383 distinct levels. The 5 lowest and the highest levels are quoted in Table XVII. The CEF splittings of the lowest $^5L_6$ and $^5K_5$ levels are given in Table XVIII. It should be noted that unlike before, the CEF operator acts not only on the $5f$ electrons but also on the $6d$ one,¹⁸

$$U^{CEF}(\vec{n}) = B_4^f \rho_f^4(\vec{n}) + B_6^f \rho_f^6(\vec{n}) + B_4^d \rho_d^4(\vec{n}). \quad (5.12)$$

TABLE XVIII: CEF low energy spectrum and magnetic moments of the $6d5f^3$ configuration of Np, $\Delta\epsilon = 1949.5$ K. CEF parameters $B_4 = -288.1$ K, $B_6 = 254.2$ K, and $B_4^d = -232.7$ K; $x_{eff} = 0$.

	Γ	deg.	$(\epsilon_i - \epsilon_1)$ (K)	$\mathcal{M}_z(\mu_B)$
$^5L_6$	A	1	0	0
	T_2	3	9.7	± 0.1809 ; 0
	A	1	12.6	0
	T_1	3	15.6	± 0.3772 ; 0
	E	2	36.4	0; 0
$^5K_5$	T_2	3	43.6	± 2.0637 ; 0
	T_1	3	$\Delta\epsilon$	± 1.7253 ; 0
	E	2	$\Delta\epsilon + 3.1$	0; 0
	T_2	3	$\Delta\epsilon + 21.1$	± 1.8006 ; 0
	T_1	3	$\Delta\epsilon + 25.3$	± 2.0883 ; 0

Here $\rho_f^l(\vec{n})$, $l = 4, 6$, and $\rho_d^4(\vec{n})$ are cubic projectors on the f and d states, respectively, given by

$$\rho_f^l(\vec{n}) = \sum_{I,J} |I\rangle \sum_a P(a) \sum_{\alpha=1}^3 \langle i_\alpha^f | K_l | j_\alpha^{af} \rangle \prod_{\beta=1}^3 \delta_{i_\beta j_\beta^a} \langle J |, \quad (5.13a)$$

$$\rho_d^4(\vec{n}) = \sum_{I,J} |I\rangle \sum_a P(a) \langle i^d | K_4 | j^{ad} \rangle \prod_{\beta=1}^3 \delta_{i_\beta j_\beta^a} \langle J |, \quad (5.13b)$$

where $K_l(\Omega)$ refers to the cubic harmonics with $l = 4$ and 6 . Here we keep the same notations as before [Eqs (4.18) and (5.9)], i.e. the permutation a transforms the indices j_1^f, j_2^f, j_3^f to j_κ^{af} , $\kappa = 1 - 3$. The permutations which interchange the d and f indices are excluded because they give zero contribution to (5.13a,b). The parameter B_4^d was calculated by the method described in Sec. IV.B. For $x_{eff} = 0$ we have found that

$$\frac{q_d^d}{(R_{MT}^{Np})^4} = 0.1287, \quad B_4^d = -232.7 \text{ K}. \quad (5.14)$$

Notice that for the ground state the CEF gives a non-magnetic single level, Table XVIII, but there are two low lying magnetic levels (T_2 and T_1) at 9.7 and 15.6 K, which contribute to the Curie law of the magnetic susceptibility at $T > 25$ K.

Below 25 K the local symmetry of Np is lowered. The mean field is given by

$$U^Q Q(\vec{n}_p) = -\Lambda^f \rho_f^Q(\vec{n}_p) - \Lambda^d \rho_d^Q(\vec{n}_p), \quad (5.15)$$

where

$$\Lambda^f = \lambda^{ff} \langle \rho_f^Q \rangle + \lambda^{fd} \langle \rho_d^Q \rangle, \quad (5.16a)$$

$$\Lambda^d = \lambda^{df} \langle \rho_f^Q \rangle + \lambda^{dd} \langle \rho_d^Q \rangle. \quad (5.16b)$$

Here again $\rho_f^Q(\vec{n})$ and $\rho_d^Q(\vec{n})$ are quadrupolar projection on the f and d states, respectively. They are given by

TABLE XIX: Mean-field (trigonal) splittings of $6d5f^3$ at $T = 0$; $\Lambda^f = 6220$ K, $\Lambda^d = 3442$ K.

Γ	deg.	$(\epsilon_i - \epsilon_1)$ (K)	$\mathcal{M}_z(\mu_B)$
A	1	0	0
E	2	32.8	± 0.4362
E	2	136.6	± 0.8797
A	1	311.2	0
A	1	337.0	0
E	2	601.2	± 1.7673

expressions similar to (5.13a-b), where we replace $K_l(\hat{n}_p)$ by $\mathcal{S}_p$, Eqs (2.1a-d), for 4 sublattices $\{n_p\} = 1 - 4$ of $Pa\bar{3}$ or $Pn\bar{3}m$, Sec. II. [Compare also with Eqs (4.18) and (5.9).] Below we approximated the parameters of this interaction by

$$\frac{q_2^d}{(R_{MT}^{Np})^2} = 0.1713, \quad \Lambda^f = 6220 \text{ K}, \quad \Lambda^d = 3442 \text{ K}. \quad (5.17)$$

We then diagonalized the whole Hamiltonian H^{MF} ($H^{MF} = U^Q Q(\vec{n}) + V_{CF} + H_{intra}$) and obtained the lowest energy levels quoted in Table XIX. Notice that now the first magnetic excitation of E symmetry is separated from the nonmagnetic ground state by an energy gap of ~ 33 K, which implies again disappearance of the Curie law for the magnetic susceptibility of the ordered phase ($T < 25$ K).

VI. DISCUSSION AND CONCLUSIONS

In resonant X-ray scattering (RXS) experiments the transition to the ordered phase at $T_c = 25.5$ K in NpO_2 manifests itself by the appearance of superstructure Bragg reflections [like (003) and others], which are not compatible with the $Fm\bar{3}m$ structure of the disordered phase.^{11,15} Paixão *et al.*, Ref. 15, ascribed the symmetry of the ordered phase to the $Pn\bar{3}m$ space group (No. 224, Ref. 22), but did not elaborate on the theory. In this work (Sec. II), besides $Pn\bar{3}m$ we discuss also the space group $Pa\bar{3}$ (No. 205), which is the other possible candidate for the triple- $\vec{q}^X$ quadrupole ordering. $Pn\bar{3}m$ and $Pa\bar{3}$ are close symmetries. They imply condensations of different modes (X_4^+ and X_5^+ , Ref. 23) at the same X -point of the Brillouin zone. We have considered the dependence of the scattering amplitude for different polarizations on the azimuthal angle ψ and the Bragg angle Θ taking into account the domain pattern of both symmetries. $Pn\bar{3}m$ and $Pa\bar{3}$ produce superstructure Bragg reflections at the same sites (h, k, l) of the reciprocal lattice (Tables I and II). The relation between the space groups is such that in RXS experiments the (00 ℓ) reflection of $Pn\bar{3}m$ behaves like the (ℓ 00) and (0 ℓ 0) reflections of $Pa\bar{3}$ ($\ell = 2n + 1$). Therefore, we believe that a special care should be taken to distinguish between these

two symmetries. We have shown that the two structures are completely different with respect to the direct bilinear quadrupole-quadrupole interactions. The $Pn\bar{3}m$ symmetry leads to a repulsion between the quadrupoles while the $Pa\bar{3}$ structure implies an attraction. (This is the main reason why the $Pa\bar{3}$ symmetry occurs in many molecular solids: NaO_2 ²⁵, N_2 ²⁷, C_{60} .^{26,28,29,30,31})

We have presented an *ab initio* approach to crystal- and mean field for the structural phase transition at 25 K. The method is based on the technique of expanding the Coulomb repulsion between electrons in a multipolar series, Sec. III.

In the disordered phase we considered the Hamiltonian which includes the crystal electric field (CEF) effects and the intrasite Coulomb repulsion responsible for Hund's rules on equal footing, Sec. IV. The crystal electric field levels above the ground state are in fact the lowest excitations of the neptunium electron complex. The typical splittings there are of the order of ten kelvins and thus the electron spectrum is very sensitive to the crystal symmetry. In this paper we have pursued the simple idea that the symmetry lowering produces a splitting of the many electron spectrum, which can explain the difference in the behavior of the magnetic susceptibility and the loss of the magnetic moments. Our band structure calculation (Sec. III.A) indicates that besides the three localized $5f$ electrons there is always approximately one conduction electron at each Np site. This changes the effective instantaneous configuration from the three electron $5f^3$ to a four electron one ($7s5f^3$, $7p5f^3$ or $6d5f^3$) and opens a possibility to obtain a nonmagnetic ground state without invoking the concept of the octupole order parameter.⁹ From this point of view it represents an alternative to the latter, and we believe that both approaches deserves a thorough experimental consideration and verification.

Our finding that the CEF splitting in NpO_2 is rather small ($\sim 50 - 150$ K) contrasts the commonly accepted value of 55 meV.⁴² We think that the excitation at 55 meV observed experimentally by neutron scattering⁴² is a higher excitation of the neptunium electronic complex possibly involving the valence electrons on the Np-O bonds. The scale of CEF excitations calculated in the present work is a better match for the width of peaks in magnetic neutron scattering cross sections.⁴² We believe that the crystal and mean field should be of the same order of magnitude and the transition temperature of 25 K gives a natural estimation for it. An implicit support of our viewpoint is the fact that in the ordered phase there appears an inelastic peak centered at about 6.4 meV.⁴²

The phase transition to the ordered phase sets in at 25 K and reduces the basic local symmetry of the neptunium sites to $S_6 = C_3 \times i$ (or $\bar{3}$). This symmetry holds for both $Pn\bar{3}m$ and $Pa\bar{3}$ space groups. [The addition of three two-fold axes or three mirror planes for $Pn\bar{3}m$ changes the point group to D_{3d} (or $\bar{3}2$) but this is not of principal importance.] We have found that the structural change can not be ascribed to the bilinear quadrupole-quadrupole

Coulomb repulsion, which is too weak to drive the transition. Therefore, one has to resort to the superexchange interactions³² via oxygen as a driving force for the transformation. In this work we have introduced an effective (enhanced) quadrupole interaction and studied the interplay between it and the crystal electric field. The influence of both interactions on the transition temperature has been investigated in detail for the $5f^3$ configuration, Sec. IV and figures 3, 4, and 5.

The most intriguing question is the disappearance of the neptunium magnetic moments below 25 K. This however can be explained if we consider a four electron complex at the neptunium site. We have demonstrated that all relevant configurations ($7s5f^3$, $7p5f^3$, $6d5f^3$) can lead to a nonmagnetic ground state separated from the magnetic excitations by an energy gap larger than ~ 25 K, Sec. V. Perhaps, the most clear example is the $7p5f^3$ configuration (Tables XV, XVI). In the disordered phase the ground state is a triplet (Table XV), while in the ordered phase it becomes a singlet (Table XVI). The general idea for the loss of magnetic moments is similar to the one used by Kondo and Anderson and often referred to as the Kondo effect.⁵¹ Notice however, that here we are dealing with the intrasite interactions treated on *ab initio* level. In particular, we replace the Anderson hybridization⁵² which is *linear* in terms of creation/annihilation operators for valence and localized electrons, by the Coulomb intrasite repulsion, which being a density-density coupling is *bilinear* in terms of these operators. Another important theoretical ingredient of our model is the symmetry lowering which modifies the excitation spectrum of the electron system at low temperatures. This part is absent in the Kondo mechanism.

CEF and mean field have been objects of theoretical interest for many years^{44,45,50,53} and we would like to mention here some important relations between our model and other approaches. We have shown that CEF effects can be perceived as a first meaningful term of the intersite multipole expansion, when all neighbors of a neptunium site are considered in the spherical approximation ($l' = 0$). It is then reduced to a single particle potential.^{44,45} The intersite nonspherical terms are also included in the full potential (FP) electron band structure calculations like FP-LMTO (linear muffin-tin orbital method) and FP-LAPW (linear augmented plane wave method).³⁹ Therefore, in principle one can say that the CEF effects are equivalent to the full potential treatment.^{46,47} However, there are two very important caveats here. First, in the band structure calculations the nonspherical terms of the potential apply to itinerant electrons in the ground state, while CEF effects are considered usually for localized electrons in the ground and *excited* states. The second more important objection is that practically all band structure calculations are based on the single determinant approximation. This intrinsic feature does not allow to describe the intrasite interactions fully. In particular, the atomic term structure and Hund's rules are excluded from the consideration. This

shortcoming does not apply to our treatment which is based on a many determinant approach. For the intrasite part of interactions our model is very close to the scheme described by Condon and Shortley for the electron spectra of atoms and ions although there are some unimportant differences. The main approximation and limitation of our approach is the choice of basis. Once the many electron basis states are fixed, the work of calculating matrix elements is reduced mainly to classifications of all possible permutations, which is done numerically. Thus, the fundamental group of electron permutations⁵⁴ is explicitly taken into account. No additional approximations used sometimes for crystal field calculations are made. This distinguishes our approach from Stevens⁵⁰ where the CEF is expressed in terms of equivalent operators J_x , J_y , and J_z . The latter approach as well as the work of Lea, Leask and Wolf for cubic CEF⁴⁹ based on it are justified only if J is a good quantum number. Notice also that the approach of Stephens starts with the symmetry arguments while the interactions are introduced later in a phenomenological manner.

However, the present calculation scheme does not take into account chemical bonding in an intrinsic way. Therefore, further development of the method should be focused on this problem.

Acknowledgments

We thank C. Detlefs, P. Santini and other authors of Ref. 15 for helpful discussions and communications on this problem. This work has been financially supported by the Fonds voor Wetenschappelijk Onderzoek, Vlaanderen.

APPENDIX A: BILINEAR QUADRUPOLE INTERACTIONS FOR $Pn\bar{3}m$ AND $Pa\bar{3}$

Here we calculate the direct bilinear electronic quadrupole-quadrupole interactions for $Pn\bar{3}m$ and $Pa\bar{3}$ structures, Fig. 1. We consider the quadrupolar components S_i of T_{2g} symmetry ($i = 1 - 3$) at site $\vec{n} = 0 \equiv (0, 0, 0)$ ($\vec{n} \in \{n_1\}$). There are 12 nearest neighbors of $\vec{n}$ belonging to three different sublattices $\{n_p\}$, $p = 1 - 3$. The interactions between three components S_i centered at $\vec{n} = 0$ and those (S_j) located at four nearest neighbors ($\vec{n}' = 1 - 4$) of the second sublattice ($\vec{n}' \in \{n_2\}$) are given in Table XX.

The matrix $S'_i(\vec{n}) - S'_j(\vec{n}')$ for the fourth sublattice $\{n_4\}$ is given by the same Table provided that the cyclic permutation $S_1 \rightarrow S_3$, $S_2 \rightarrow S'_1$, $S_3 \rightarrow S'_2$ is performed. Here we label four nearest neighbors $\vec{n}' = 5 - 8$ of $\vec{n}$ as $5 \equiv a(1/2, 1/2, 0)$, $6 \equiv a(-1/2, 1/2, 0)$, $7 \equiv a(-1/2, -1/2, 0)$, and $8 \equiv a(1/2, -1/2, 0)$. The matrix $S''_i(\vec{n}) - S''_j(\vec{n}')$ for the third sublattice $\{n_3\}$ is obtained from Table XX by replacing $S_1 \rightarrow S''_2$, $S_2 \rightarrow S''_3$, $S_3 \rightarrow S''_1$. Here $\vec{n}'$ runs

TABLE XX: The matrix of interaction $S_i(\vec{n}) - S_j(\vec{n}')$ between three quadrupolar components of T_{2g} symmetry, $S_1 = Y_2^{1s}$, $S_2 = Y_2^{1c}$, $S_3 = Y_2^{2s}$. S_i are centered at $\vec{n} = (0, 0, 0)$, S_j at four neighbors $\vec{n}'$ of the second sublattice $\{n_2\}$.

$\vec{n}'$	Coord.	$(i, j) =$	(1,1)	(2,2)	(3,3)	(1,2)	(1,3)	(2,3)
1	$a(0, \frac{1}{2}, \frac{1}{2})$	γ	α	α	0	0	β	
2	$a(0, -\frac{1}{2}, \frac{1}{2})$	γ	α	α	0	0	$-\beta$	
3	$a(0, -\frac{1}{2}, -\frac{1}{2})$	γ	α	α	0	0	β	
4	$a(0, \frac{1}{2}, -\frac{1}{2})$	γ	α	α	0	0	$-\beta$	

over the sites $9 \equiv a(1/2, 0, 1/2)$, $10 \equiv a(-1/2, 0, 1/2)$, $11 \equiv a(-1/2, 0, -1/2)$, and $12 \equiv a(1/2, 0, -1/2)$.

For the $Pn\bar{3}m$ order of quadrupoles we have $\mathcal{S}_a$, Eq. (2.1a), at $(0, 0, 0)$ and $\mathcal{S}_d$, Eq. (2.1d), for $\vec{n}' = 1 - 4$. By means of Table XX we find that this interaction is given by

$$E_0^{QQ}(\{n_2\}) = \frac{4}{3}(\gamma - 2\alpha). \quad (A1)$$

The same expression is obtained for the interactions with four neighbors of third and forth sublattices, $E_0^{QQ}(\{n_3\})$ and $E_0^{QQ}(\{n_4\})$. The total interaction then is

$$\begin{aligned} E^{QQ}(Pn\bar{3}m) &= E_0^{QQ}(\{n_2\}) + E_0^{QQ}(\{n_3\}) + E_0^{QQ}(\{n_4\}) \\ &= 4(\gamma - 2\alpha) > 0, \end{aligned} \quad (A2)$$

because $\gamma > 0$ and $\alpha < 0$ independently of the lattice constant a .

For the $Pa\bar{3}$ structure we have the function $\mathcal{S}_b$, Eq. (2.1b), at $\vec{n}' = 1 - 4$, and $E_0^{QQ}(\{n_2\}) = -4\gamma/3$. The same value is obtained for $E_0^{QQ}(\{n_3\})$ and $E_0^{QQ}(\{n_4\})$. As a result we arrive at

$$E^{QQ}(Pa\bar{3}) = -4\gamma < 0. \quad (A3)$$

We conclude that the $Pn\bar{3}m$ structure always leads to a repulsion while the $Pa\bar{3}$ to an attraction.

APPENDIX B: CORRECTION OF SLATER INTEGRALS FOR NP

Since the experimental data on the energy splittings of the $4f^3$ configuration of Pr^{3+} and Nd^{4+} are available from the atomic database of NIST, Ref. 43, while there is no such information for $5f^3$, we have performed calculations of v_l^{F-F} ($l = 2, 4, 6$), Eq. (3.18a), by using the radial dependence of $\mathcal{R}_f$ obtained from LDA calculations of atoms. After this we diagonalize the Hamiltonian of the free ion ($V^{(3)} + H_{so}$) and compared our calculated spectra with the experimental ones. We have noticed that the comparison is improved (the sequence of terms corresponds to the experimental one) if we reduce v_2^{F-F} and v_6^{F-F} by a factor of 0.75 while keep v_4^{F-F} almost the same (factor 0.975). Therefore, we have used the same scale factors for Np in NpO_2 and obtained parameters given by Eq. (4.3).
